STAT has been applied for misuse detection in UNIX systems, distributed systems, and networks. USTAT is the first prototype of STAT, which is aimed at misuse detection in UNIX systems (Ilgun et al. 1995). It relies on Sun Microsystems’ C2- Basic Security Module (BSM) to collect audit records. In addition to detecting attacks, USTAT is designed to be a real-time system that can preempt an attack before any damage can be done. USTAT was later extended to process audit data collected on multiple UNIX hosts. The resulting system is NSTAT, which runs multiple daemon programs on the hosts being protected to read and forward audit data to a centralized server, which performs STAT analysis on all data.

A later application of STAT to network-based misuse detection resulted in another system, named *NetSTAT* (Vigna and Kemmerer 1999). In this work, the network topology is further modeled as a hypergraph. Network interfaces, hosts, and links are considered the constituent elements of hypergraphs, with interfaces as the nodes, and hosts and links as hyperedges. Using the network-topology model and the state-transition description of network-based attacks, NetSTAT can map intrusion scenarios to specific network configurations and generate and distribute the activities to be monitored at certain places in a network.

STAT was intended to be a high-level tool to help specify attack patterns. Using STAT, the task of describing an attack scenario is expected to be easier than using rule-based languages, although the analysis required to understand the nature of attacks remains the same. In the implementations of STAT techniques (i.e., USTAT, NSTAT, and NetSTAT), the attack scenarios are transformed into rule bases, which are enforced by a forward-chaining inference engine.

Colored Petri Automata

Kumar and Spafford (1994) and Kumar (1995) viewed misuse detection as a pattern-matching process. They proposed an abstract hierarchy for classifying intrusion signatures (i.e., attack patterns) based on the structural interrelationships among the events that compose the signature. Events in such a hierarchy are high-level events that can be defined in terms of low-level audit trail events and used to instantiate the abstract hierarchy into a concrete one. A benefit of this classification scheme is

that it clarifies the complexity of detecting the signatures in each level of the hierarchy. In addition, it also identifies the requirements that patterns in all categories of the classification must meet to represent the full range of commonly occurring intrusions (i.e., the specification of context, actions, and invariants in intrusion patterns).

Kumar and Spafford adopted colored Petri nets to represent attack signatures, with guards to represent signature contexts and vertices to represent system states. User-specified actions (e.g., assignments to variables) may be associated with such patterns and then executed when patterns are matched. The adapted colored Petri nets are called “colored Petri automata” (CPA). A CPA represents the transition of system states along paths that lead to intruded states. A CPA is also associated with pre- and postconditions that must be satisfied before and after the match, as well as invariants (i.e., conditions) that must be satisfied while the pattern is being matched. CPA has been implemented in a prototype misuse-detection system called intrusion detection in our time (IDIOT).

CPA is quite expressive; it provides the ability to specify partial orders, which in turn subsume sequences and regular expressions. However, if improperly used, the expressiveness may lead to potential problems: If the intrusions are described in every detail, the attacker may be able to change his/her attacking strategy and bypass the IDSs. Nevertheless, CPA is not the root of the problem.

Abstraction-Based Intrusion Detection

Many misuse-detection approaches share a common problem in their implementation: Each system is written for a single environment and has proved difficult to use in other environments that may have similar policies and concerns. The primary goal of abstraction-based intrusion detection is to address this problem.

The initial attempt of the abstraction-based approach is a misuse-detection system named the adaptable real-time misuse-detection system (ARMD) (Lin, Wang, and Jajodia 1998). ARMD provides a high-level language for abstract misuse signatures, called MuSigs, and a mechanism to translate MuSigs into a monitoring program. With the notion of abstract events, the high-level language specifies a MuSig as a pattern over a sequence of abstract events, which is described as conditions that the abstract event attributes must satisfy. The gap between abstract events and audit records is bridged by an audit subsystem, which transforms the actual audit records into abstract events. In addition, on the basis of MuSigs, the available audit trail, and the strategy costs, ARMD uses a strategy generator to automatically generate monitoring strategies to govern the misuse-detection process.

ARMD is a host-based misuse-detection system. In addition to the features mentioned above, it also uses database query-optimization techniques to speed up the processing of audit events. The experiences with ARMD show that knowing the characteristics of the audit trail helps estimate the cost of performing misuse detection and gives the security officers the opportunity to tune the misuse-detection system.

A limitation of ARMD is that it requires users to have a precise understanding of the attacks and to make careful

plans for the abstraction of events. This planning is not an easy job, especially when a user does not know how his/her MuSigs may be used. In particular, unforeseen attacks may invalidate previously defined abstract events and MuSigs, thus forcing the redevelopment of some or all of the MuSigs.

The work by Ning, Jajodia, and Wang (2001) further extends the result in ARMD to address the aforementioned limitation. It provides a framework for distributed attack specification and event abstraction. In this framework, abstraction is considered an ongoing process. The structures of abstract events are represented as system views, and attack signatures are represented as generic patterns on the basis of system views. This new approach allows the semantics of a system view to be modified by defining new signatures and view definitions without changing the specifications of the views or the signatures specified on the basis of the system views. As a result, signatures in this model can potentially accommodate unknown variants of known attack patterns. Although the specification of attack signatures and the choice of right abstraction still partially depend on the users' skill, this framework provides guidance and alleviates the burden of writing and maintaining signatures.

Automatic Generation of Attack Signatures

Most commercial IDSs are misuse-detection systems that rely on attack signatures to identify attacks. The ability of an IDS to detect attacks is highly affected by the quality of the attack signatures used for detection. Most signatures used in existing IDSs were manually crafted by human users after they understood the nature of the attacks. However, it has been commonly agreed that manually generating attack signatures is time-consuming and error-prone. In particular, there is no hope of manually generating attack signatures for fast-spreading attacks such as worms to effectively detect and stop such attacks. In this section, we discuss several attempts to generate attack signatures automatically, starting with the influential work by Lee and Stolfo.

Data Mining Framework for Building Attack Models

Lee and Stolfo (2000) looked at intrusion detection as a data-analysis process and applied several data-mining techniques to build misuse-detection models. The research efforts were conducted under a project entitled JAM, the Java Agent for Meta-learning (meta-learning is a general strategy that provides the means of learning how to combine and integrate a number of separately learned classifiers or models). In particular, association rules and frequent episodes are used to automatically discover features that should be used to model a subject's behavior, and the meta classification is used to combine the results of different classifiers to get better classification results. This framework uses a “supervised” learning approach to build attack models. In other words, it requires that records of the training datasets used for building attack modes be labeled as either normal or intrusive.

Lee and Stolfo extended the original association rules to take into account the “order of importance” relations among the system features (the notion of an association

rule was discussed above regarding ADAM). *Axis* refers to the features that are important to intrusion detection; only the association rules involving axis features are considered. For example, in the shell command records, the command is likely to reflect the intrusive activities and thus be identified as an axis feature. In some sense, axis features incorporate expert knowledge into the system and thus improve the effectiveness of association rules.

To represent frequent sequential patterns of network events, Lee and Stolfo (2000) extended frequent episodes, which was originally proposed by Mannila, Toivonen, and Verkamo (1995), to represent the sequential interaudit record patterns. Their algorithm finds frequent sequential patterns in two phases. First, it finds the frequent associations among event attributes using the axis attributes, and then it generates the frequent sequential patterns from these associations. The algorithm also takes advantage of the "reference" relations among the system features. That is, when forming an episode, the event records covered by the constituent item sets of the episode share the same value for a given feature attribute. The mined frequent episodes are used to construct temporal statistical features, which are used to build classification models. Thus, new features can be derived from the training data set and then used for generating better intrusion-detection models.

Another innovation of the JAM project is meta classification, which combines the output of several base classifiers and generates the best results out of them. Specifically, from the predictions of base classifiers and the correct classes, a meta classifier learns which base classifier can make the best prediction for each type of input. It then chooses the prediction of the best base classifier for different inputs and combines the powers of the base classifiers.

Lee and Stolfo (2000) advanced state-of-the-art knowledge of intrusion detection by introducing the MADAMID (mining audit data for automated models for intrusion detection) framework that helps generate intrusion-detection models automatically. The limitation is that the framework depends on the volume of the evidences. That is, intrusive activities must generate a relatively noticeable set of events so the association of event attributes or frequent episodes can reflect them. Thus, the generated models must work with some other complementary systems, such as STAT.

Automatic Signature Generation and Intrusion Prevention

Fast-spreading worms (e.g., Code Red, SQL Slammer, Blaster) motivated the investigation of more efficient and effective defense mechanisms that can stop such attacks. Initial attempts include Autograph (Kim and Karp 2004), EarlyBird (Singh et al. 2004), and Polygraph (Newsome, Karp, and Song 2005). One common goal of these approaches is to automatically and quickly generate attack signatures from worm attack traffic, so that these attack signatures can be deployed at content-based firewalls elsewhere to stop the spread of (previously unknown) worm attacks. Despite the difference in technical details, these approaches share some common features. Given a set of worm traffic, all these approaches identify the byte sequences that are common to this type of traffic,

and use such byte sequences as signatures for the worms. A limitation of these approaches is that they all extract signatures in a syntactic manner, while ignoring the semantics of the attacks. This limitation makes these approaches vulnerable to polymorphic and metamorphic worms. Polymorphic worms change their binary representations while they spread through semantic manipulation of their code representation. Similarly, metamorphic worms evade detection via encryption (with different keys) while they spread. As a result, the worm traffic may not have common substrings that are good enough to distinguish them from normal traffic, thus making these syntactic approaches not as effective as expected.

Several recent approaches attempt to generate attack signatures by exploiting the semantics of victim programs and attacks to address the aforementioned problem. A notable approach is TaintCheck (Newsome, Karp, and Song 2005), which performs dynamic taint analysis (via binary program emulation) to track the propagation of network input data, and raise alerts (and at the same time stop the attacks) when such data are directly or indirectly used illegitimately (e.g., a network input is used as the target of a jump instruction). TaintCheck generates semantic-based attack signatures from the network input data that eventually leads to an alert. Because TaintCheck has access to the history of the program execution, it has the information to pinpoint the invariable content (e.g., vulnerable memory address to be exploited) in attack packets, and thus can potentially generate attack signatures more precisely than the aforementioned syntactic approaches. Another example is the automatic diagnosis and response mechanism studied by Xu et al. 2005. This method is aimed at automatically identifying (unknown) memory corruption vulnerabilities, which are the dominant target of worm attacks. Based on the observation that a randomized program usually has an extremely high probability of crashing upon such attacks, this method uses a crash of a randomized program as a trigger to start the automatic diagnosis of memory corruption vulnerabilities, and traces back to the vulnerable instructions that corrupts memory data upon a memory corruption attack. The output of the diagnostic process includes the instruction exploited by the attacker to corrupt critical program data, the stack trace at the time of the memory corruption, the history that the corrupted data is propagated after the initial data corruption, and a signature of the attack exploiting the vulnerabilities. Such a signature consists of the program state at the time of attack and the memory address values used in the attack, allowing efficient and effective protection of the vulnerable program by filtering out future attacks. Wang, Cretu, and Stolfo (2005) took a different approach to automatically generating attack signatures by correlating (and identifying the longest common subsequence of) ingress and egress malicious payloads. Though most of these approaches are still works in progress, they certainly have demonstrated the potential of semantic-based signatures. We expect to see substantial advances in this direction in the next few years.

A closely related issue is evaluation of attack signatures. That is, how well can an attack signature detect attacks (including their variations)? Vigna et al. (2004) developed an approach to evaluating attack signatures by generating variations of known attacks (called "mutant

attacks”) through manipulating attack packets. Rubin, Jha, and Miller (2004) developed an approach to inferring all variations of an attack using language-based techniques. We refer readers to these papers.

Limitation of Misuse Detection

Current misuse-detection systems usually work better than anomaly-detection systems for known attacks. That is, misuse-detection systems detect patterns of known attacks more accurately and generate much fewer false alarms. This better performance occurs because misuse-detection systems take advantage of explicit knowledge of the attacks.

The limitation of misuse detection is that it cannot detect novel or unknown attacks. As a result, the computer systems protected solely by misuse-detection systems face the risk of being compromised without detecting the attacks. In addition, because of the requirement of explicit representation of attacks, misuse detection requires the nature of the attacks to be well understood. This implies that human experts must work on the analysis and representation of attacks, which is usually time consuming and error prone. Several ongoing works (e.g., Lee and Stolfo 2000; Newsome, Karp, and Song 2005; Xu et al. 2005) are targeting this problem by automatically generating attack signatures and preventing attacks in-progress.

INTRUSION-DETECTION SYSTEMS

Host-Based Intrusion-Detection Systems

As discussed earlier in the chapter, host-based IDSs get security audit data from individual hosts, and usually are aimed at detecting attacks against a single host. Several techniques we have discussed in earlier sections can be used for host-based IDSs—for example, the statistical models, the specification-based method, and the computer immunological approach. There are both advantages and disadvantages of using host-based IDSs. On the positive side, host-based IDSs can access more information on the host, and thus can usually make more accurate decisions about attacks. On the negative side, running a host-based IDS on an operational machine that runs critical services will add performance overheads to the host, thus degrading the performance.

There have been a lot of debates about whether host-based IDSs should be adopted or entirely discarded. Advances in attacks and detection techniques seem to indicate that host-based IDSs are necessary parts of a comprehensive defense system. There are two reasons. First, as discussed earlier, worms have adopted polymorphic and metamorphic techniques to evade detection. In both cases, it is difficult to identify patterns of worm attack traffic that do not match normal network traffic. Second, protocols with encryption (such as secure socket shell [SSH] and secure sockets layer [SSL]) are more and more widely adopted by Internet users. It is impossible to detect attacks carried in encrypted payloads through network-based IDSs. In contrast, it is convenient for host-based IDSs to get precise information about attacks, including the semantics of the programs that are potentially attacked.

Intrusion Detection in Distributed Systems

The rapid growth of the Internet not only provides the means for resource and information sharing, but it also brings new challenges to the intrusion-detection community. Because of the complexity and the amount of audit data generated by large-scale systems, host-based IDSs, though helpful for protecting large-scale systems through protection of individual hosts, are not sufficient by themselves. It is highly desirable to have complementary techniques that can detect and respond to attacks against large-scale systems.

Research on intrusion detection in distributed systems has been focused on two essential issues: *scalability* and *heterogeneity*. The IDSs in large distributed systems need to be scalable to accommodate the large amount of audit data in such systems. In addition, such IDSs must be able to deal with heterogeneous information from component systems of different types and that constitute large distributed systems and can cooperate with other types of IDSs.

Research on distributed intrusion detection is being conducted in three main areas. First, people are building scalable, distributed IDSs or are extending existing IDSs to make them capable of being scaled up for large systems. Second, network-based IDSs are being developed to take advantage of the standard network protocols to avoid heterogeneous audit data from different platforms. Third, standards and techniques are being developed to facilitate information sharing among different, possibly heterogeneous IDSs.

Distributed Intrusion Detection Systems

Early distributed IDSs collect audit data in a distributed manner but analyze the data in a centralized place—for example DIDS (Snapp et al. 1991) and ASAX (Mounji et al. 1995). Although audit data are usually reduced before being sent to the central analysis unit, the scalability of such systems is still limited. When the size of the distributed system grows large, not only might audit data have to travel long distances before arriving at the central place, but the central analysis component of the IDS may be overwhelmed by large amounts of audit data being generated.

Systems such as EMERALD (Lindqvist and Porras 1999), GrIDS (graph-based intrusion detection systems; Axelsson 1999), and AAFID (the autonomous agents for intrusion detection system; Spafford and Zamboni 2000), pay more attention to the scalability issue. To scale up to large distributed systems, these systems place IDS components in various places in a distributed system. Each of these components receives audit data or alerts from a limited number of sources (e.g., hosts or other IDS components), so the system is not overwhelmed by large amounts of audit data. Different components are often organized hierarchically in a tree structure; lower-level IDS components disseminate their detection results to higher-level components, so the intrusion-related information from different locations can be correlated together.

Although most of the recent distributed IDSs are designed to be scalable, they provide only a partial solution to the scalability problem. The IDS components are either

coordinated in an ad hoc way or are organized hierarchically. Although coordinating the IDS components in an ad hoc way is certainly not a general solution, organizing the components hierarchically does not always provide an efficient solution, especially when the suspicious activities are spread in different, unpredictable locations in a large system. In a hierarchical system, when the activities involved in a distributed attack fall beyond the scope of one IDS component, the audit data possibly related to the attack will have to be forwarded to a higher-level IDS component to be correlated with data from other places. In a worst-case scenario, the audit data may have to be forwarded several times before arriving at a place where the data can finally be correlated with the related information. This process not only wastes the network's bandwidth, it also limits the scalability of the detection of distributed attacks.

Abstraction-based intrusion detection (Ning, Jajodia, and Wang 2001) addresses this problem by generating a hierarchy of IDS components dynamically rather than statically. Intuitively, this method defines attack signatures as generic patterns (called "generic signatures") of abstract events that may be observed in different places in a distributed system. When a particular type of attack is to be detected in a distributed system, the corresponding generic signature is mapped to the specific systems. The resulting signature is called a "specific signature." This method then decomposes the specific signature into components called "detection tasks," each of which corresponds to the intrusion-detection activities required to process a type of event involved in the attack. A coordination mechanism is developed to arrange the messages passing between the detection tasks, so the distributed detection of attacks is equivalent to having all events processed in a central place. The abstraction-based method is more flexible and more efficient than the previous methods; however, it is limited in that it is applicable only to misuse detection.

Network-Based Intrusion-Detection Systems

Network-based IDSs collect audit data from the network traffic, in contrast to host-based IDSs, which usually collect audit data from host audit trails. Examples of network-based IDSs include NSM (Network Security Monitor; Axelsson 1999), NetSTAT (Vigna and Kemmerer 1999), and Bro (Axelsson 1999).

One challenge that network-based intrusion detection is facing is the speed of high-performance networks, which makes it very difficult to capture the network traffic, let alone perform intrusion detection in real time. Several efforts have addressed enabling intrusion detection in high-speed networks. Snort, an open source IDS that specializes in network intrusion detection (Snort 2002), was developed by Roesch (1999). It uses a fast pattern-matching algorithm to detect network misuse. However, early versions of Snort detected attacks individually, and its performance degrades when the number of attack signatures (rules) increases. Since version 1.9, Snort has incorporated new pattern-matching algorithms to address this problem.

Sekar et al. (1999) developed a high-performance network-IDS-based on an efficient pattern-matching

algorithm. A distinguishing feature is that the performance of the system is independent of the number of misuse rules (signatures).

Kruegel et al. (2002) proposed a partition approach to intrusion detection that supports misuse detection on high-speed network links. This approach is based on a slicing mechanism that divides the overall network traffic into subsets of manageable size. Thus, each subset can be processed by one or several misuse-detection systems. The traffic partitioning is done such that each subset of the network traffic contains all the evidence necessary to detect a specific attack.

Network-based IDSs offer several advantages. First, network-based IDSs can take advantage of the standard structure of network protocols, such as TCP/IP. This is a good way to avoid the confusion resulting from heterogeneity in a distributed system. Second, network-based IDSs usually run on a separate (dedicated) computer; thus, they do not consume the resources of the computers that are being protected.

Conversely, network-based IDS are not silver bullets. First, because these IDSs do not use host-based information, they may miss the opportunity to detect some attacks. For example, network-based IDSs cannot detect an attack launched from a console. Second, the standard network protocols do not solve the entire problem related to the heterogeneity of distributed systems because of the variety of application protocols and systems that use these protocols. For example, network-based IDSs must understand the UNIX shell commands if their goal is to monitor intrusive remote log-ins. As another example, network-based IDSs usually describe the suspicious network activities using the structure of the packet that standard network protocols such as TCP/IP support, which makes the specification of the suspicious activities to be detected very difficult.

Network-based IDSs have the same scalability problem as do general distributed IDSs. For example, existing network-based IDSs analyze network traffic data in a centralized place, as was done by the early distributed IDSs, although they may collect data from various places in the network. This structure limits the scale of the distributed systems that such IDSs can protect.

Sharing Information among Intrusion-Detection Systems

With the deployment of so many commercial IDSs, these IDSs must be able to share information so that they can interact and thus achieve better performance than if they were operating in isolation. Research and development activities are currently under way to enable different, possibly heterogeneous, IDSs to share information.

The common intrusion-detection framework (CIDF) was developed to enable different intrusion detection and response (IDR) components to interoperate and share information and resources (Porras et al. 1999). It began as a part of the Defense Advanced Research Project Agency (DARPA) Information Survivability program, with a focus on allowing DARPA projects to work together. CIDF considers IDR systems as composed of four types of components that communicate via message passing: event

generators (E-boxes), event analyzers (A-boxes), event databases (D-boxes), and response units (R-boxes). A communication framework and a common intrusion-specification language are provided to assist the interoperation among CIDF components.

Researchers involved in CIDF started an Intrusion Detection Working Group (IDWG) in the Internet Engineering Task Force (IETF), trying to bring the impact of CIDF to a broader community. The IDWG has been working to develop data formats and exchange procedures for sharing information among IDSs, response systems, and management systems. The extensible markup language (XML) has been chosen to provide the common format, and an intrusion-detection message exchange format (IDMEF) has been defined in an Internet draft. The IDWG uses the blocks extensible exchange protocol (BEEP) as the application protocol framework for exchanging intrusion-detection messages between different systems; an intrusion-detection exchange protocol (IDXP) is specified as a BEEP profile, and a tunnel profile is provided to enable different systems to exchange messages through firewalls.

Another effort in sharing information among different IDSs is the Hummer project (Frincke et al. 1998). In particular, the relationships among different IDSs (e.g., peer, friend, manager/subordinate) and policy issues (e.g., access-control policy, cooperation policy) were studied, and a prototype system, HummingBird, was developed to address these issues. A limitation of the Hummer project is that it addresses only the general data-sharing issue; what information needs to be shared and how the information would be used are out of its scope. Thus, it should be used along with mechanisms such as IDIAN (Feiertag et al. 2000) and the decentralized coordination mechanism in the abstraction-based approach (Ning, Jajodia, and Wang 2001).

There are several ongoing efforts to facilitate the sharing of intrusion related data. Examples include DShield (<http://www.dshield.org>) and the PREDICT project (<http://www.predict.org>). A common goal of these projects is to collect data about intrusions from different regions and different organizations to facilitate intrusion analysis. However, these activities also raised legal and privacy concerns of the organizations that provide such data. Several research groups have investigated techniques that can allow access to the valuable information and at the same time can protect the privacy of the data providers (Lincoln et al. 2004; Xu and Ning 2005)

INTRUSION-ALERT CORRELATION

Traditional IDSs focus on low-level attacks or anomalies, and raise alerts independently, though there may be logical connections between them. In situations in which there are intensive attacks, not only will actual alerts be mixed with false alerts, but the number of alerts will also become unmanageable. As a result, it is difficult for human users or intrusion-response systems to understand the alerts and take appropriate actions. Therefore, it is necessary to develop techniques to correlate IDS alerts and construct attack scenarios (i.e., steps that attackers use in their attacks) to facilitate intrusion analysis.

In this section, we first give a brief overview of the techniques for intrusion-alert correlation, and then present in more detail one approach that correlates intrusion alerts based on prerequisites and consequences of known attacks.

Techniques for intrusion-alert correlation can be divided into several classes. The first class of approaches (e.g., Spice [Staniford, Hoagland, and McAlerney 2002] and probabilistic alert correlation [Valdes and Skinner 2001]) correlates IDS alerts based on the similarities between alert attributes. They usually require a distance function to measure the similarity between two IDS alerts based on the alert attribute values, and correlate two alerts together if the distance between them is less than a certain threshold. Though they are effective for clustering similar alerts (e.g., alerts with the same source and destination IP addresses), they cannot fully discover the causal relationships between related alerts.

The second class of methods (e.g., correlation based on STATL [Eckmann, Vigna, and Kemmerer, 2002]) performs alert correlation based on attack scenarios specified by human users, or learned from training data sets. Such methods are essentially extensions to misuse detection. Similar to misuse detection, intrusion-alert correlation based on known scenarios are effective in recognizing known attack scenarios, but are also restricted to known attack scenarios, or those that can be generalized from known scenarios. A variation in this class uses a consequence mechanism to specify what types of attacks may follow a given attack, partially addressing this problem (Debar and Wespi, 2001).

The third class of methods (e.g., JIGSAW [Templeton and Levitt 2000], the MIRADOR correlation method [Cuppens and Mieke 2002], and the correlation method based on prerequisites and consequences of attacks [Ning, Cui, and Reeves, 2002]) targets recognition of multistage attacks; it correlates alerts if the prerequisites of some later alerts are satisfied by the consequences of some earlier alerts. Such methods can potentially uncover the causal relationship between alerts, and are not restricted to known attack scenarios. We will discuss one such method in detail later in this chapter.

The fourth class of methods attempts to correlate alerts (including IDS alerts) from multiple sources, using potentially complementary information to improve the understanding of possible intrusions. A formal model named M2D2 was proposed in Morin et al. (2002) to correlate alerts by using multiple information sources, including the characteristics of the monitored systems, the vulnerability information, the information about the monitoring tools, and information of the observed events. Because of the multiple information sources used in alert correlation, this method can potentially lead to better results than those simply looking at intrusion alerts. A mission-impact-based approach was proposed by Porras, Fong, and Valdes (2002) to correlate alerts raised by information security devices such as IDSs and firewalls. A distinguishing feature of this approach is that it correlates the alerts with the importance of system assets so that attention can be focused on critical resources. Though methods in this class are still in their preliminary stage, we believe techniques in this class will

eventually provide the most support for intrusion-alert analysis.

Intrusion-Alert Correlation Based on Prerequisites and Consequences of Attacks

To further illustrate intrusion-alert correlation techniques, we give additional details about the alert correlation method based on prerequisites and consequences of attacks (Ning, Cui, & Reeves 2002), which one of us was involved in developing.

The alert-correlation model is based on the observation that in series of attacks, the component attacks are usually not isolated, but related as different stages of the attacks, with the early ones preparing for the later ones. For example, an attacker has to install distributed denial of service (DDoS) daemon programs before he can launch a DDoS attack. To take advantage of this observation, it correlates alerts using prerequisites and consequences of the corresponding attacks. Intuitively, the *prerequisite* of an attack is the necessary condition for the attack to be successful. For example, the existence of a vulnerable service is the prerequisite of a remote buffer overflow attack against the service. Moreover, an attacker may make progress (e.g., install a Trojan horse program) as a result of an attack. Informally, the possible outcome of an attack is called the *consequence* of the attack. In a series of attacks in which earlier ones are launched to prepare for later ones, there are usually connections between the consequences of the earlier attacks and the prerequisites of the later ones. Accordingly, this method identifies the prerequisites (e.g., existence of vulnerable services) and the consequences (e.g., discovery of vulnerable services) of attacks, and correlates detected attacks (i.e., alerts) by matching the consequences of previous alerts and the prerequisites of later ones.

Predicates are used as basic constructs to represent prerequisites and consequences of attacks. For example, a scanning attack may discover UDP (user datagram protocol) services vulnerable to certain buffer overflow attacks. We can use the predicate *UDPVulnerableToBOF* (*VictimIP*, *VictimPort*) to represent this discovery. In general, a logical formula (i.e., a logical combination of predicates) is used to represent the prerequisite of an attack. Thus, we may have a prerequisite of the form *UDPVulnerableToBOF* (*VictimIP*, *VictimPort*) $\wedge$ *UDPAccessibleViaFirewall* (*VictimIP*, *VictimPort*). Similarly, a set of logical formulas is used to represent the consequence of an attack.

With predicates as basic constructs, a *hyper-alert type* is used to encode our knowledge about each type of

attack. A *hyper-alert type* T is a triple (*fact*, *prerequisite*, *consequence*) in which: (1) *fact* is a set of attribute names, each with an associated domain of values, (2) *prerequisite* is a logical formula whose free variables are all in *fact*, and (3) *consequence* is a set of logical formulas such that all the free variables in *consequence* are in *fact*. Intuitively, the *fact* component of a hyper-alert type gives the information associated with the alert, *prerequisite* specifies what must be true for the attack to be successful, and *consequence* describes what could be true if the attack indeed happens. For brevity, we omit the domains associated with attribute names when they are clear from context.

Given a hyper-alert type $T = (\text{fact}, \text{prerequisite}, \text{consequence})$, a *hyper-alert (instance)* h of type T is a finite set of tuples on *fact*, where each tuple is associated with an interval-based timestamp [*begin_time*, *end_time*]. The hyper-alert h implies that *prerequisite* must evaluate to True and all the logical formulas in *consequence* might evaluate to True for each of the tuples. The *fact* component of a hyper-alert type is essentially a relation schema (as in relational databases), and a hyper-alert is a relation instance of this schema. A hyper-alert *instantiates* its *prerequisite* and *consequence* by replacing the free variables in *prerequisite* and *consequence* with its specific values. Note that *prerequisite* and *consequence* can be instantiated multiple times if *fact* consists of multiple tuples. For example, if an IPSweep attack involves several IP addresses, the *prerequisite* and *consequence* of the corresponding hyper-alert type will be instantiated for each of these addresses.

To correlate hyper-alerts, this method checks whether an earlier hyper-alert contributes to the prerequisite of a later one. Specifically, it decomposes the prerequisite of a hyper-alert into parts of predicates and tests whether the consequence of an earlier hyper-alert makes some parts of the prerequisite True (i.e., makes the prerequisite easier to satisfy). If the result is positive, then the hyper-alerts are correlated together. In the formal model, given an instance h of the hyper-alert type $T = (\text{fact}, \text{prerequisite}, \text{consequence})$, the *prerequisite set* (or *consequence set*) of h , denoted $P(h)$ (or $C(h)$), is the set of all such predicates that appear in *prerequisite* (or *consequence*) whose arguments are replaced with the corresponding attribute values of each tuple in h . Each element in $P(h)$ (or $C(h)$) is associated with the timestamp of the corresponding tuple in h . A hyper-alert h_1 *prepares for* hyper-alert h_2 if there exist $p \in P(h_2)$ and $C \subseteq C(h_1)$ such that for all $c \in C$, $c.\text{end\_time} < p.\text{begin\_time}$ and the conjunction of all the logical formulas in C implies p .

Figure 1: A hyper-alert correlation graph

Given a sequence S of hyper-alerts, a hyper-alert h in S is a *correlated hyper-alert* if there exists another hyper-alert h' such that either h prepares for h' or h' prepares for h . A *hyper-alert correlation graph* is used to represent a set of correlated hyper-alerts. Specifically, a *hyper-alert correlation graph* $CG = (N, E)$ is a connected graph, where N is a set of hyper-alerts and for each pair $n_1, n_2 \in N$, there is a directed edge from n_1 to n_2 in E if and only if n_1 prepares for n_2 .

Figure 1 shows one of the hyper-alert correlation graphs discovered in an experiment with the 2000 DARPA intrusion-detection evaluation data sets. Each node in Figure 1 represents a hyper-alert, where the label inside the node is the hyper-alert type followed by the hyper-alert ID. This hyper-alert correlation graph shows an attack scenario in which the attacker probes for vulnerable *Sadmind* service, compromises the vulnerable service using a buffer overflow attack, copies some file with *Rsh*, starts a DDOS daemon program named *mstream*, and finally launch a DDOS attack.

CONCLUSION

Intrusion detection continues to be an active research field, and it is undergoing a fast transition. Even after over 20 years of research, the intrusion-detection community still faces several difficult problems. How to detect unknown patterns of attacks without generating too many false alerts remains an unresolved problem, although several results have shown there is a potential resolution to this problem. The evaluation and benchmarking of IDSs is also an important problem, which, once solved, may provide useful guidance for organizational decision makers and end users. (Some results on evaluating IDSs can be found in McHugh [2000].) Reconstructing attack scenarios from intrusion alerts and integration of IDSs will improve both the usability and the performance of IDSs. How to prevent attacks while detecting these attacks (i.e., intrusion prevention) is also a critical issue affecting the deployment of IDSs. Many researchers and practitioners are actively addressing these problems. We expect intrusion detection to become a practical and effective solution for protecting information systems.

This chapter is by no means a complete reference for intrusion-detection systems; many important issues have not been included because of space constraints. Further readings are suggested at the end of this chapter.

GLOSSARY

Anomaly Detection: One of the two methods of intrusion detection. Anomaly detection is based on the normal behavior of a subject (e.g., a user or a system); any action that significantly deviates from the normal behavior is considered intrusive. More generally, anomaly detection refers to identification of potential system security policy violations based on observation that some action or other characteristics deviate from normal. The underlying philosophy is that “normal” or acceptable behaviors and other features can be described, and deviations from them recognized. The other method is misuse detection.

Audit Trail: Records a chronology of system-resource usage. This includes user log-in, file access, other various activities, and whether any actual or attempted security violations occurred.

False Negative: An actual misuse action that the system allows to pass as non-misuse behavior.

False Positive: Classification of an action as anomalous (a possible instance of misuse) when it is legitimate.

IDS: Intrusion detection system.

Intrusion: Any activity that violates the security policy of an information system, normally ascribed to a system outsider who “enters” the system to perform this behavior, but sometimes used more generally to cover any violation of policy. Also referred to as “misuse.”

Intrusion Detection: The process of identifying intrusions or other misuses by observing security logs, audit data, or other information available in computer systems and/or networks.

Intrusion-Alert Correlation: The process to identify related intrusion alerts and the relationship between them. The goal is often to reconstruct the attack scenarios (i.e., steps of attacks) from the intrusion alerts reported by the IDS; alternatively, it may be used to recognize broad-based attacks even without regard to specific steps.

Misuse Detection: One of the two methods of intrusion detection, often but not necessarily used to scrutinize representations of behavior. Catches intrusions in terms of the characteristics of known patterns of attacks or system vulnerabilities; any action that conforms to the pattern of a known attack or vulnerability is considered intrusive. More generally, misuse detection refers to identification of violations of system-security policy based on recognizing actions or other characteristics known to be associated with such violations. The philosophy behind misuse detection is that inappropriate activities or behaviors can be characterized, and used to detect policy violations. The other method is anomaly detection.

Misuse Signature: A known pattern or attack or vulnerability, usually specified in a certain attack-specification language.

Profile: A set of parameters used to represent the pattern of a subject’s (e.g., a user or a program) normal behavior. It is normally used to conduct anomaly detection.

Security Policy: A set of rules and procedures regulating the use of information, including its processing, storage, distribution, and presentation.

FURTHER READING

This chapter serves as an introduction to intrusion detection. The reader may want to read more on this subject to gain a full picture of the state of the art of intrusion detection. A book titled *Intrusion Detection* (Bace 1999) gives a nice overview of intrusion-detection techniques and systems prior to the late 1990s. Another book, titled *Network Intrusion Detection* (Northcutt and Novak 2002) provides a wonderful guideline for practical network intrusion detection. DARPA (Defense Advanced

Research Projects Agency) provided substantial support for intrusion-detection research in the late 1990s and early 2000s, including the 1998 and 1999 DARPA Intrusion Detection Evaluation program led by researchers at the MIT Lincoln Laboratory. DARPA-supported researchers made substantial progresses in intrusion detection, which were mostly reported in the Proceedings of DARPA Information Survivability Conference and Exposition (DISCEX) (<http://csdl2.computer.org/persagen/DLPublication.jsp?pubtype=p&acronym=DISCEX>). Another good source for the recent advances in intrusion-detection research is the Proceedings of the International Symposia on Recent Advances in Intrusion Detection (RAID) (<http://www.raid-symposium.org/>).

INTRODUCTION

The last decades of the twentieth century were characterized by the rise of new technologies that support most of the strategic and critical activities. Energy, manufacturing, water resources, geology, and press are just few applications that are evolving by leaps and bounds on the impulse of the computer and communication locomotive. Having followed the mechanical and industrial revolutions, these developments have been so important that their traces are ever-present. The widespread use of advanced computer and network technologies has allowed the automation of certain key processes and the fast transmission of important data. Obviously, this has resulted in a noteworthy gain, especially in terms of time and effort, which magnifies productivity. Nevertheless, advances in these areas have also been linked to huge losses because of the improper use of the network computing infrastructure. The functionalities provided by the modern networked information systems have been exploited by attackers and victims alike. Even though the existing protection infrastructures are being continuously improved, they are overawed by the power of the attackers' capabilities.

The purpose of this chapter is to convey to the reader the problems of defining and modeling network attacks, the pervasiveness and impact of these attacks, and how one can develop a cost-effective security platform when encountering such security incidents.

The remainder of this chapter is structured as follows. The section on security incidents introduces the basic terminology that is used throughout the chapter and points out the main features of network attacks. The next section reviews the importance of the attack outcome analysis. It also identifies several new attack trends. We

next focus on various attack techniques and discusses some useful attack taxonomies. The next section explains the need for building attack models to achieve different objectives (e.g., detection, prevention, reaction). And the subsequent section analyzes the features of two types of models: the preventive models and reactive models. Next, three major aspects of network attack response are covered: building the security policy, monitoring the network state, and handling security incidents. A set of general guidelines to choose the more suitable security solutions is given in the section titled "Countermeasure-Selection Guidelines." The final section examines the most relevant challenges faced by the security community.

DESCRIPTION OF SECURITY INCIDENTS

Intrusions, threats, and alerts are three concepts that are similar in the sense that they represent attacks; but they are also different because they actually refer to different aspects of the attack process. In this section, a set of definitions that highlight the slight differences between attacks, intrusions, threats, and alerts are proposed. In addition, the characteristics of the information conveyed by each of these terms are investigated.

Threats, Alerts, and Intrusions

A *threat* is any event that can result in a loss for the target system. It can be malevolent, accidental, or even due to a natural disaster. Threat modeling is an important practice that provides the capability to secure a network environment. It is critical to be aware of the types of threats and how to reduce or mitigate the risk both in systems

and applications on network devices. In fact, reaching an accurate description of a specific threat clearly allows identifying the best techniques that protect the system against it. Modeling a threat mainly includes identifying the vulnerabilities to which it relates, and structuring incidents in a way that facilitates the communication of threat information throughout the network computing environment. This turns out to be a difficult process because the security analyst should look for the events that might occur and anticipate how the malicious user could harm the protected system. Typically, the information that should be associated with a specific threat breaks into three components: probability, outcome, and exploited vulnerability.

An *alert* can be loosely defined as a description of an attack that is achieved by monitoring several system parameters. Alert generation is an event triggered by the occurrence of a network attack. The main role of alert generation is that it allows the security analyst to identify the attacks that are carried out against the system to proceed to the appropriate reaction. However, the alert-attack association is never certain, and a single alert can be related to more than one attack. Hence, mechanisms to determine the *most probable* attack linked to a specific alert should be available. Generally, the decision errors that confuse the alert-based incident response break into two categories: (1) false positives (i.e., an alert is generated in the absence of a network attack), and (2) false negatives (i.e., no alert is generated when an attack did occur). Obviously, both of these errors result in a loss, and their probability should be therefore minimized to enhance the efficiency of the intrusion-detection process. *Probability* defines the amount of uncertainty related to the attack event, and *impact* provides an idea about the severity of a specific threat. It is often assessed on the basis of the nature of the victim network asset. Generally, threats that are characterized by important probability and impact values are prioritized. The exploited vulnerability should be included in the threat information to facilitate the countermeasure-selection process.

To explain what an intrusion is, some fundamentals about security policy should be given. In its broadest definition, a *security policy* consists of a set of rules that define how critical assets should be secured. Based on this definition, an intrusion in an information system can be thought of as an activity that does not respect the system's security policy. In other terms, an action that violates one or more security property (i.e., confidentiality, integrity, availability) of the protected system is considered as an intrusion. As an extension to this reasoning, an attack against a communication network is not perceived as an intrusion if it does not violate the security rules of the target system. In this case, the attack is not detected at the time and the only information available for the response team is the intrusion outcome; consequently, novel rules should be appended to the security policy to prevent future occurrences of the experienced attack. Typically, when a system experiences an attack that has not been noticed by the detection infrastructure, a forensic activity should be conducted in order to reconstitute the instruction scheme and decide the novel rules to append.

Basic Attack Features

It comes from the previous subsection that a network attack is rather an abstract concept, which is represented by some pieces of information that may vary according to the situation. For instance, in the context of threat analysis, the information one is seeking is the knowledge of whether a security breach has been experienced, and, if the answer is yes, what are the probability and the impact. Conversely, when studying an alert, the main concern is to identify the malicious action that is being carried out in order to react at the convenient moment and in a cost-effective manner. Despite the pervasiveness of network attacks, several fundamental characteristics should be taken into consideration independently from the way the attack is viewed. Analyzing those common features is helpful in the sense that it conveys a better understanding of both the attacker behavior and the defense capabilities. The most prominent attack characteristics can be summarized in the following points:

Coordination

To achieve a major objective, the attacker often combines multiple elementary attacks or uses several external resources. This is because organized attacks aiming at disrupting critical infrastructure are beyond the capabilities of a single attacker. Therefore, multiple attackers can cooperate by resource sharing, task allocation, and time synchronization. Obviously, such attacks are more difficult to detect and to counter. The most important problems associated with these attacks are given in the following:

Coordinated attacks are difficult to detect: Many intrusion-detection systems (IDSs) can be defeated by coordinated attacks capable of breaking the attack scheme into many apparently inoffensive actions. For instance, if we consider a large set of users, hosts, processes, and threads with few attackers hiding a coordinated attack plan, it is practically impossible to discern individual attackers because of the huge amount of data that would be analyzed. In addition, many of those attackers would appear to perform innocuous actions.

Differentiating between decoy and actual attacks is difficult: Often, numerous attacks are conducted against a system in a nearly simultaneous manner. In order to mislead the IDS, all but a small number of these attacks are designed to be decoys, meaning that they are carried out for the sole purpose of distracting the intrusion-response system and consuming its resources. Decoy attacks may have different goals. They could: create simultaneous alerts in order to alter the efficiency of the intrusion response system; waste system response resources on decoy goals; or perform a denial-of-service attack on the IDS.

There is a large variety of coordinated attacks: Intruders may attack single or multiple victims. Some attacks could be automatically replicated in order to accumulate more power. Other attacks may be carried out in parallel from multiple attackers (or network nodes that are under the control of the attacker) targeting a single victim.

Incomplete Knowledge

Threats and alerts, which are often used to select the optimal set of countermeasures for a specific attack scenario, are characterized by an amount of uncertainty. This uncertainty should be taken into consideration when making decisions based on threat or alert representation of network attacks. Practically, threats and alerts are used to select the best set of countermeasures according to a cost-benefit balance. On the one hand, modeling a threat allows thwarting the attack before its occurrence by adding rules to the security policy. On the other hand, alerts provide a strong means for reacting against intrusions. Models used to represent threats and alerts should therefore integrate uncertainty-handling mechanisms (e.g., probabilistic, fuzzy logic-based) to measure the lack of information about the original attack. Most of the algorithms proposed in the literature to deal with this aspect rely on uncertain decision making by associating a probability of occurrence to a specific threat and a measure of efficiency to the intrusion-detection tool (Lee et al. 2002; Wei et al. 2001).

Handling the Attack Information

At this level, the reader may be wondering about the practical use of the aforementioned attack-related concepts. Actually, threats and alerts are two key components of the risk-management framework, which consists of integrating security in the business process of the enterprise. Both threats and alerts are helpful for conducting an efficient and cost-effective decision-making process. In the following, we underline the importance of threat and alert analysis in the risk-management process.

Generally, risk analysis breaks into three elementary activities (Hamdi and Boudriga 2005, Computer and network security risk management): (1) threat analysis, which consists of estimating the probability, outcome, and exploited vulnerability associated with a threat, (2) business impact analysis (BIA), which consists of evaluating the effect of the occurrence an attack against a given asset, and (3) cost-benefit analysis (CBA), which consists of comparing the cost and the benefit of the available countermeasures to select the most convenient ones. The two last aspects are beyond the scope of this chapter, and will not be detailed.

Peltier (2001) affirmed that threat analysis should involve the examination of three basic elements: (1) the agent, which is the entity that carries out the attack, (2) the motive, which is the reason that causes the agent to act, and (3) the results, which are the outcomes of the occurrence of the attack. Another element that can be added to the aforementioned ones is the attack mechanism. This key factor can serve to differentiate between threats that share the same agent, motive, and results by highlighting the weakness that would be exploited by the attacker. In addition, analyzing the steps to carry out a harmful action is helpful for automating several tasks, such as the selection of appropriate solutions. Threat modeling has often been linked to the vulnerability-analysis process, which consists of identifying the security breaches in a specific system. This encompasses a security assessment that

takes into account operating systems (OSs), applications, protocols, and network topologies. Consequently, a huge amount of data must be accurately collected and scanned. Unfortunately, most of the existing risk-management (RM) methods reduce vulnerability analysis to vulnerability identification and thus subordinate many key issues. For example, OCTAVE (Alberts and Dorofee 2002) defines this activity as “running vulnerability evaluation tools on selected infrastructure components.” A similar definition has been given by Ozier (1999): “*This task includes the qualitative identification of vulnerabilities that could increase the frequency or impact of threat event(s) affecting the target environment.*” It appears from these definitions that the goal of vulnerability analysis has been commonly viewed as ascertaining the existence of a set of vulnerabilities in several components of a given system. In other terms, the risk analyst has to map some elements of the vulnerability library to each asset of the studied system. Nevertheless, this task can be more skillfully applied by considering the following concepts:

Vulnerability-Detection Strategies

Security specialists should be aware of the various testing methods that can be applied to detect vulnerabilities. The choice of a testing strategy depends on the nature of the weakness and the characteristics of the target system. Automated vulnerability testing strategies break into two categories: black-box testing and white-box testing. The former consists of evaluating the behavior of the system without having a precise idea about its constituency, while the latter presupposes that the source code of the tested entity (e.g., piece of software, OS, and communication protocol) is available. Most of the existing vulnerability-detection methods belong to the black-box class (e.g., rule-based testing, penetration-based testing, and inference-based testing).

Vulnerability-Identification Techniques

Many vulnerability-detection mechanisms are available. Thus, the most convenient ones should be selected according to the need of the risk analyst. Many static white-box testing techniques have been evolved and discussed. The more basic one is related to the use of the **gets()** function within C programs. This function normally captures strings from the standard input, but it has been demonstrated to be vulnerable to buffer-overflow errors because it does not test the size of this input (Krsul, Spafford, and Tripunitara 1998). Likewise, Bishop and Dilger (1996) focused on a specific type of software errors called “time-of-check-to-time-of-use” (TOCTTOU). These race-condition errors occur when a function or a piece of program is executed without checking to see whether it yields a secure state. A known example resides in set user ID (SUID)-root programs in UNIX-based environments that check the access permissions to a file and modify it directly without checking to see whether this security property still holds after the modification. Viega et al. (2000) give 12 rules that prevent several errors in Java code. Ghosh et al. (1996) proposed a white-box dynamic security-testing technique that relies on two main principles: random input generation and fault injection. Input generation gives the risk analyst the ability

to generate a set of test values that will be submitted to the analyzed program as inputs in order to study its behavior. Fault injection is the process of perturbing the execution of a program by introducing several insecure states.

Vulnerability-Library Structure

The vulnerability library can contain thousands of security weaknesses. Therefore, it must be structured in a manner to support various types of queries. Vulnerability information is customary structured in various manners, including traditional (i.e., relational) databases, mailing lists, and newsletters. The most important vulnerability databases (VDBs) are the following:

The Computer Emergency Response Team (CERT) Advisories: CERTs publish warnings related to the most important, and most recent, vulnerabilities. They collect information about different types of security incidents. After analyzing these events, a report including the possible exploits and the related countermeasures is established.

The MITRE Common Vulnerability and Exposures (CVE) list: CVE is defined as a “standardized list of names for vulnerabilities and other information security exposures.” Substantially, CVE is not a database; nevertheless, it is very helpful when the risk analyst uses data from different VDBs. Practically, within the risk-management framework, multiple vulnerability scanners are used for a more complete list of detected weaknesses. In this case, CVE can serve to fuse the data emanating from those tools into a unified list.

The Bugtraq mailing list: This archive basically consists of a mailing list that allows security specialists to exchange information and to share their knowledge. Its main limitation is that the focused vulnerabilities and exploits concern only Windows-based operating systems.

The NIST meta-base: The National Vulnerability Database is a CVE-based VDB that offers interesting search possibilities. It may link the user to other vulnerability databases where more detailed information can be found, or it can even redirect the user toward Web resources where accurate defense solutions can be found. ICAT is probably the most complete VDB, as it “indexes the information available in CERT advisories, ISS X-Force, Security Focus, NTBugtraq, Bugtraq, and a variety of vendor security and patch bulletins.” Hence, it would be considered as a meta-base that can be use as a search engine rather than a VDB itself.

ANALYZING THE ATTACKER’S OBJECTIVES

The number of services that are (partially or completely) provided via modern communication infrastructures and information systems is growing explosively. Unfortunately, as these systems get more sophisticated, so do the attacks carried out against them. Effectively, it appears that every attack is linked to one or more specific services. This section addresses the relationship between the attacker’s goals and the characteristics of the target service. More precisely, several factors, such as the

proportionality of the complexity of the attack process to the budget spent to conduct it will be investigated. Finally, novel attack trends will be explored based on intruder activity during recent years.

The Attack/Service Relationship

Several services offered by networked infrastructures are more vulnerable than others. This subsection provides a detailed discussion of the characteristics that might increase the attractiveness of a service to the attacker.

First, the weakness of a service is linked to its scalability. In fact, if a service is intended for a large number of users, the authentication and access-control mechanisms that are used to protect are rarely strict. This is mainly for three reasons:

1. When the number of users is important, the client community becomes heterogeneous and the enterprise that manages the service should deal with a mixing of specialists and nonexperts. And nonspecialists often feel reluctant to adhere to strong security policies, especially when there are additional costs involved as compared with the intrinsic cost of the service. The enterprise then chooses simple authentication schemes, which are not necessarily in conformance with its security objectives. In addition, a wider and heterogeneous client community is more likely to include malicious users.
2. The cost of handling the authentication credentials and the access-control system increases with respect to the size of the client population. In other words, the scalability of the security infrastructure itself should be considered. Hence, enterprises tend to avoid complex security mechanisms that become hard to administer for a large network.
3. If the service is distributed among multiple countries, the legal aspects should be discussed, and this sometimes weakens the security level of the policy rules. For instance, consider the case in which a virtual private network (VPN) is used to interconnect internationally distributed subsidiary companies, and suppose that the VPN nodes are authenticated on the basis of digital certificates. The problem that may arise in such situations is that a cross-certification agreement must exist between the certification authorities that generate the different certificates. Such agreement is not usually easy to achieve because of the divergence of local certification laws, architectures, and policies.

Furthermore, it appears that distributed services are more vulnerable to network attacks. This is due to the lack of security at the distributed-component level. Enterprises seldom dedicate additional security equipment or skilled staff to these components, which become key elements to launch various types of attacks.

In the Arbor Worldwide ISP [Internet service provider] Security Survey (Arbor Networks 2005), the majority of respondents indicated that gambling and adult content Web sites are the most frequent targets of denial of service attacks. Internet relay chat (IRC) infrastructures are also often attacked. This means that the nature of the

population that connects to a specific Web site can also be an indicator of the threat likelihood.

Correlating Attack Complexity and Attack Severity

The Arbor Worldwide ISP Security Survey cited two major threats facing network operators:

Distributed Denial of Service (DDoS)—The survey states that “Despite concern in the press and research communities about the evolving complexity of backbone attacks, most providers reported that the majority of DDoS attacks exhibited relatively simple brute-force attack vectors.” Effectively, more than 90 percent of the respondents reported that transmission control protocol (TCP) synchronization (SYN) and user datagram protocol (UDP) flooding attacks, which are among the simplest DoS techniques, are the primary source of threats against their infrastructures;

Worms—Worms rank second in the list of the most reported attacks (Arbor Networks 2005). According to ISPs, the actual loss related to worms does not reside in their payload but rather in the network congestions they cause. It has been noticed that the flow corresponding to a single attack may range from 500Mbps to 8Gbps.

Simple attacks continue to constitute the greatest source of damage, despite the appearance of sophisticated protection tools. This idea is reinforced by the analysis of the dollar amount losses by type of attack reported in the 2005 CSI/FBI threat report (Gordon et al. 2005). The results, which are summarized in Figure 1 show that viruses generated the most important losses during 2005. It should be also pointed out that “Unauthorized access” and “Proprietary information theft” have been the source of significant damages.

Available protection strategies have not been very successful in limiting the impact of the attacks. One of the key factors is that multiple security mechanisms are needed to ensure an acceptable security level. These mechanisms should be distributed on all the network components. In fact, several attacks, such as worms, must be stopped at the client level (by installing patches and antivirus programs) but also at the ISP level to avoid congestion. Security solutions should also be associated with strategies and guidelines that are necessary to promote the awareness of the enterprises’ personnel. This view regarding security problems encompasses a division of the global networked infrastructure into domains that should be secured using different techniques. For instance, each enterprise would be responsible for the security of its domain, consisting of the assets belonging to its private network.

Noteworthy Shifts in Network Attack Techniques

In addition to the aforementioned surveys, other studies and surveys (Australian High Tech Crime Centre 2005; Department of Trade and Industry (UK) 2004) have shown that new trends are emerging with the appearance of novel attack categories and the decay of other categories. In the following, six trends that have shaped the attackers’ behavior are discussed.

Trend 1: Virus-Based Attacks Are Deceasing

Figure 2 shows that the number of virus-based attacks has decreased considerably in the United States. This is confirmed by other surveys carried out in other countries (e.g., the United Kingdom and Australia). However, malicious codes, and worms in particular, have sustained the outcome of most of the remaining threats, especially from a network perspective. This means that antivirus programs are no longer sufficient to counter this type of

Figure 1: Dollar amount losses by threat type in the United States. Source: 2005 CSI/FBI threat annual report

Figure 2: Types of attacks experienced by U.S. enterprises. *Source:* CSI/FBI Annual Report, 2000–2005

digital attack. Network-anomaly-based monitoring tools should be used to enhance defense capabilities.

Trend 2: Attack Tools Are Increasingly Sophisticated

The level of automation in attack tools continues to increase. Automated attacks commonly involve four phases, each of which is changing.

1. Scanning for potential weaknesses. Widespread scanning has been common since 1997. Today, scanning tools are using more advanced scanning patterns to maximize impact and speed.
2. Compromising vulnerable systems. Previously, the scanning activity was limited to vulnerability identification. To perform effective intrusions, attackers had to look for separate autonomous programs and scripts. Now, attack tools exploit vulnerabilities as a part of the scanning activity, which increases the speed of propagation.
3. Propagating the outcome. Before 2000, attack tools required a person to initiate additional attack cycles. Today, attack tools can self-initiate new attack cycles. Tools like Code Red and Nimda, for example, self-propagate to a point of global saturation in less than 18 hours.
4. Using composite attacks. Since 1999, with the advent of distributed attack tools, attackers have been able to manage and coordinate large numbers of deployed attack tools distributed across many Internet systems. Today, distributed attack tools are capable of launching denial of service attacks more efficiently, scanning for potential victims and compromising vulnerable systems. Coordination functions now take advantage of readily available, public communications protocols

such as Internet relay chat (IRC) and instant messaging (IM).

Trend 3: Attacks Are Becoming More Robust against Detection Mechanisms

Attack-tool developers are using more advanced techniques than previously. Attack-tool signatures are more difficult to discover through analysis and more difficult to detect through signature-based systems such as antivirus software and intrusion-detection systems. Three important characteristics are the antiforensic nature, dynamic behavior, and modularity of the tools.

1. Antiforensics. Attackers use techniques that obfuscate the nature of attack tools. This makes it more difficult and time consuming for security experts to analyze new attack tools and to understand new and rapidly developing threats. Analysis often includes laboratory testing and reverse engineering.
2. Dynamic behavior. Early attack tools performed attack steps in single defined sequences. Today's automated attack tools can vary their patterns and behaviors based on random selection, predefined decision paths, or through direct intruder management.
3. Modularity of attack tools. Unlike early attack tools that implemented one type of attack, tools now can be changed quickly by upgrading or replacing portions of the tool. This causes rapidly evolving attacks and, at the extreme, polymorphic tools that self-evolve to be different in each instance.

In addition, attack tools are more commonly being developed to execute on multiple operating system platforms. As an example of the difficulties posed by sophisticated attack

tools, many common tools use protocols like IRC or HTTP (hypertext transfer protocol) to send data or commands from the intruder to compromised hosts. As a result, it has become increasingly difficult to distinguish attack signatures from normal, legitimate network traffic.

Security of a networked system is, by nature, highly dependent on the security of the elementary components. Each Internet system's exposure to attack depends on the state of security of the rest of the systems attached to the global Internet. Because of the advances in attack technology, a single attacker can relatively easily use a large number of distributed systems to launch devastating attacks against a single victim. As the automation of deployment and the sophistication of attack-tool management both increase, the asymmetric nature of the emerging threats will continue to grow. There are three basic types of asymmetric attacks:

- consumption of computational resources, such as bandwidth, disk space, or CPU time
- disruption of configuration information, such as routing information
- disruption of physical network components

Trend 4: Firewalls and IDSs Are Increasingly Permeable

Firewalls are often relied on to provide primary protection from intruders. However, technologies are being designed to bypass typical firewall configurations; for example, IPP (the Internet printing protocol) and Web-DAV (Web-based distributed authoring and versioning). In addition, some protocols marketed as being “firewall-friendly” are, in reality, designed to bypass typical firewall configurations.

Certain aspects of “mobile-code” (ActiveX controls, Java, and JavaScript) make it difficult for vulnerable systems to be protected and malicious software to be discovered. Furthermore, IDSs are being continuously targeted by several evasive attacks. Evasion is not only the process of totally concealing an attack but it can also be a technique to make an attack appear less threatening than it really is. Attacks based on basic string matching weaknesses are among the easiest to implement and understand. Signature-based IDS devices rely almost entirely on string matching, and breaking the string match of a poorly written signature is trivial. Polymorphic shell code is a more dangerous, recently developed evasion tactic that IDS devices cannot so easily defend against. This technique is limited to buffer overflows, and is much more effective against signature-based systems than against anomaly-based or protocol analysis-based systems.

Trend 5: Decreasing Threat from Internal Attacks

Figure 3 shows that the number of attacks from outside the victim enterprises decreased in the United States during 2005. The Australian 2005 threat report corroborates this result, as the sources of 81 percent of attacks against Australian enterprises were external versus internal (37 percent). Nonetheless, fewer respondents experienced external incidents as compared with 2004 and 2003 (88 percent and 90 percent, respectively).

Figure 3: Number of attacks from inside and outside sources

Trend 6: Increasing Threat from Infrastructure Attacks

Infrastructure attacks broadly affect key components of the Internet. They are of increasing concern because of the number of organizations and users on the Internet and their increasing dependency on the Internet to carry out day-to-day business. Four types of infrastructure attacks are described briefly below.

Attack 1: Distributed denial of service. Denial-of-service attacks use multiple systems to attack one or more victim systems with the intent of denying service to legitimate users of those systems. The degree of automation in attack tools enables a single attacker to install their tools and control tens of thousands of compromised systems for use in attacks.

Intruders often search address blocks known to contain high concentrations of vulnerable systems with high-speed connections. Cable modem, digital subscriber line (DSL), and university address blocks are increasingly targeted by intruders planning to install their attack tools. Denial-of-service attacks are effective because the Internet is composed of limited and consumable resources, and Internet security is highly interdependent.

Attack 2: Worms. A worm is self-propagating malicious code. Unlike a virus, which requires a user to do something to continue the propagation, a worm can propagate by itself. The highly automated nature of the worms coupled with the relatively widespread nature of the vulnerabilities they exploit allows a large number of systems to be compromised within a matter of hours (for example, Code Red infected more than 250,000 systems in just 9 hours on July 19, 2001). Some worms include built-in denial-of-service attack payloads (e.g., Code Red) or Website defacement payloads (sadmind/IIS, Code Red); and others have dynamic configuration capabilities (W32/Leaves). But the biggest impact of these worms is that their propagation effectively creates a denial of service in many parts of the Internet because of the huge amounts

of scan traffic generated, and they cause much collateral damage (examples include DSL routers that crash; cable modem ISPs whose networks are completely overloaded, not by the scanning itself but by the burst of underlying network-management traffic that the scanning triggers; and printers that crash or print reams of junk output).

Attack 3: Attacks on the Internet Domain Name System (DNS). DNS is the distributed, hierarchical global directory that translates names (www.example.com) to numeric IP addresses (192.168.13.2). The top two layers of the hierarchy are critical to the operation of the Internet. In the top layer are thirteen root-name servers. Next are the top-level domain (TLD) servers, which are authoritative for .com, .net, etc., as well as the country code TLDs (ccTLDs—us, .uk, .tn, etc). Threats to DNS include the following:

Cache poisoning: If DNS is made to cache bogus information, the attacker can redirect traffic intended for a legitimate site to a site under the attacker's control. A survey by the CERT/Coordination Center shows that over 80 percent of the TLDs are running on servers that are potentially vulnerable to this form of attack.

Compromised data: Attackers compromise vulnerable DNS servers, giving the attackers the ability to modify the data served to users. Many of the TLD servers run a software program called Berkeley Internet Name Domain, in which vulnerabilities are discovered regularly. A CERT/Coordination Center survey indicates that at least 20 percent of TLDs are running on vulnerable servers; another 70 percent are "status unknown."

Denial of service: A large denial-of-service attack on some of the name servers for a TLD (for example, .com) could cause widespread Internet slowdowns or effective outages.

Domain hijacking: By leveraging insecure mechanisms used by customers to update their domain registration information, attackers can co-opt the domain registration processes to take control of legitimate domains.

Attack 4: Attacks Against or Using Routers. Routers are specialized computers that direct traffic on the Internet (similar to mail-routing facilities in the postal service). Threats fall into the following categories:

Routers as attack platforms: Intruders use poorly secured routers as platforms for generating attack traffic at other sites, or for scanning or reconnaissance.

Denial of service: Although routers are designed to pass large amounts of traffic through them, they often are not capable of handling the same amount of traffic directed at them. (Think of it as the difference between sorting mail and reading it.) Intruders take advantage of this characteristic by attacking the routers that lead into a network rather than attacking the systems on the network directly.

Exploitation of trust relationship between routers: For routers to do their job, they have to know where to send the traffic they receive. They do this by sharing routing information between them, which requires the routers

to trust the information they receive from their peers. As a result, it would be relatively easy for an attacker to modify, delete, or inject routes into the global Internet routing tables to redirect traffic destined for one network to another, effectively causing a denial of service to both (one because no traffic is being routed to it, and the other because it is getting more traffic than it should). Although the technology has been widely available for some time, many networks (ISPs and large corporations) do not protect themselves with the strong encryption and authentication features available on the routers.

ATTACK TECHNIQUES

This section discusses some of the most known attack schemes and shows, through concrete examples, how these attacks can be combined. For a more extensive idea about these attacks, the reader should refer to Anderson (2001) and Huang and Lee (2004).

Most-Cited Attacks

The most-cited attacks can be classified into six categories based on the technique they use.

Flooding Attacks

These attacks use the nature of a communication protocol and flood a target with a specific packet. Three flooding attacks can be considered:

- *SYN flood:* The SYN flood attack consists simply of sending a large number of SYN packets and never acknowledging any of the replies (i.e., SYN-ACK). This violation of the TCP handshake leads the recipient to accumulate more records of SYN packets than the software (implementing the TCP/IP stack) can handle. The most popular version of the attack does not reveal the actual IP address of the hacker. In fact, the return address associated with the initial SYN packets is in this case not valid; therefore, the victim would return the SYN-ACK packet to an address that does not respond or even does not exist. A technical fix, called SYNcookie, has been found and incorporated in the Linux OS in 1996 (since, it has been extended to some other OSs). Rather than keeping a copy of the incoming SYN packet, the victim simply uses a sequence number that is derived from the sequence number of the attacker (i.e., the host that initiates the connection).
- *Smurf attack:* This attack exploits the Internet control message protocol (ICMP), which enables users to send an echo packet to a remote host to check whether it is alive. The problem arises with broadcast addresses that correspond to more than one host. Some implementations of the Internet protocols respond to pings to both the broadcast address and their local address (the idea was to test a local area network [LAN] to gather the hosts that are alive). The attack is to construct a packet with the source address forged to be that of the victim, and send it to a number of Smurf amplifiers that will each respond (if alive) by sending a packet to the target; this can swamp the target with more packets than it can cope with.

- *Tribe Flood Network (TFN)*: TFN is made up of client and daemon programs, which implement a distributed network denial of service tool capable of waging ICMP flood, SYN flood, UDP flood, and Smurf style attacks. The attacker(s) control one or more clients, each of which can control many daemons. The daemons are all instructed to coordinate a packet-based attack against one or more victim systems by the client. This reduces the chances of the victim to “survive” the flooding attack because it would face hundreds (even thousands) of machines instead of a single attacker. This type of attack also hides the identity of the attack source.

Buffer-Overflow Attacks

The attacks exploit the procedure call flow to execute nonauthorized commands. From one point of view, a procedure call alters the flow of control just as a jump does, but unlike a jump, when finished performing its task, a function returns control to the statement or instruction following the call. Basically, a buffer overflow is the result of stuffing more data into a buffer than it can handle. It allows the attacker to change the return address of a function so that the attacker can change the flow of execution of the program. Typically, the return pointer of a given function is replaced by the address of the nonauthorized process (or command) that the attacker wants to execute.

Spoofing Attacks

In a spoofing attack, a user appears to be someone else—that is, the attacker fakes his identity to be that of a legitimate user. Because of spoofing, that attacker is able to manipulate packets so that they appear to come from another system or network. Thus, spoofing could include spoofing an internal network IP address or return e-mail address. This attack technique is customarily used to prepare for perpetrating flooding or other denial-of-service attacks. Spoofing covers a large category of computer attacks. It basically stands for identity falsification or masquerading. This attack class includes IP address spoofing, session hijacking, DNS spoofing, sequence-number spoofing, and replay attacks.

For example, in the case of sequence-number spoofing, the attacker must monitor the packets sent from A to B and then guess the sequence number of the packets. Then the attacker knocks out A with spoofed packets, claiming to have the address of A. A's firewall can defend against spoof attacks when it has been configured with knowledge of all the IP addresses connected to each of its interfaces. It can then detect a spoofed packet if it arrives from an interface that is not known to be connected to that interface. Many carelessly designed protocols are subject to spoof attacks, including many of those used on the Internet.

Another kind of spoofing is “Web page spoofing,” also known as *phishing*. In this attack, a Web page is made to look like a legitimate server, but is owned and operated by someone else. This attack is intended to make victims think that they are connected to a trusted site. Typically, a payment system's log-in page might be spoofed, allowing the attacker to harvest user names and passwords. This is often performed with the aid of DNS cache poisoning in order to direct the user away from the legitimate site and to the false one. Once the user puts in her password, the

attack-code reports a password error, and then redirects the user back to the legitimate site.

Sniffing Attacks

Sniffing attacks use protocol analyzers to capture network traffic for passwords and other confidential data. In many network setups, it is possible for any machine on a given network to hear the traffic for every machine on that network. This is true for most Ethernet-based networks, and Ethernet is by far the most common LAN technology in use today. This characteristic of Ethernet is especially dangerous, because most of the protocols in use today are unencrypted. As a result, the data sent and received are there for anybody to snoop on. These data include files accessed via network file systems, passwords sent to remote systems during Telnet, file transfer protocol (FTP), and rlogin sessions; e-mail sent and received; and so on. A password sniffer is a program that takes advantage of this characteristic to monitor all of the IP traffic on its part of the network. By capturing the first 128 bytes of every FTP or Telnet session, for example, password sniffers can easily pick up your username and password as you type them. Password sniffers may use programs provided for network debugging as building blocks, or may be written to use the services directly. Special-purpose password sniffing toolkits are widely available to attackers.

The danger of password sniffing attacks is in their rapid spread. Favorite targets for sniffers are network providers and public access systems, in which the volume of Telnet and FTP connections is huge. One sniffer on large public access systems can collect thousands of sniffed account names and passwords, and then compromise every system accessed. Even if your systems are as secure as possible and your user passwords are not guessable, you can be infected by a packet sniffer running at any site that your users can log in from, or at any site their packets will cross to get to you.

Sniffing attacks are among the most difficult to handle because the use of sniffing software can seldom be prohibited. Sniffers have many legitimate uses that system administrators should be aware of. They can be used to find what computers on the network are causing problems, such as using too much bandwidth, having the wrong network settings, or running malware.

Scanning Attacks

A port scan is one of the most popular reconnaissance techniques attackers use to discover services they can break into. All machines connected to a LAN or Internet run many services that listen at well-known and not-so-well-known ports. A port scan helps the attacker find which ports are available (i.e., what service might be listening to a port). Essentially, a port scan consists of sending a message to each port, one at a time. The kind of response received indicates whether the port is used and can therefore be probed further for weakness.

Routing Attacks in Mobile Ad Hoc Networks

In an ad hoc network, a malicious node intentionally drops control packets, misroutes data, or disseminates incorrect information about its neighbors and/or its prediscovered

routing capabilities to particular destinations. An attacker might try to:

- forge messages by spoofing originator or destination addresses
- signal false route errors or modify route error messages
- alter or replace originator, destination or sender addresses in routed messages

The attacker might also try to consume network resources by:

- initiating large numbers of route requests to bogus destinations in order to exhaust the resources of the network
- playing the “gray hole attack” or “selective dropping” of packets, resulting in increased numbers of route requests from neighbor nodes that have limited routing capabilities, exhausting neighbors’ resources

Network Attack Taxonomies

In the early security approaches, security incidents were broken into categories of disclosure of confidential information (loss of confidentiality), loss of integrity, and denial-of-service (DoS [loss of availability]) attacks (Amoroso 1994). However, with the spread of sophisticated attack techniques, one could assert that some other form of taxonomies needed to be developed. This section will review the most important taxonomies in the literature describing types of computer misuse and the perpetrators who perform that misuse. The taxonomies of Anderson (1980) and Neumann and Parker (1989) are covered; as well as the extension of Neumann and Parker made by Lindqvist and Jonsson (1998) and the network security taxonomy of Jayaram and Morse (1997).

Anderson’s Penetration Matrix

This taxonomy develops a four-cell matrix that covers the types of penetrators, based on whether they are authorized to use the computer and the data/program source. Relying on this idea, three major attack classes have been considered:

Class A: External Penetration, referring to attacks that are sourced from the protected system itself

Class B: Internal Penetration, referring to attacks that are sourced from outside the protected system:

- a. The masquerader (defeats procedural controls)
- b. The legitimate user
- c. The clandestine user (defeats logical controls)

Class C: Mifedance (authorized action in an improper way)

Neumann and Parker’s Method

In 1989, Neumann and Parker published, “A Summary of Computer Misuse Techniques,” in which they outlined a series of classes of computer misuse from their data of about 3000 cases over nearly twenty years. Nine categories of computer misuse, referred to as NP1 to NP9 have

been considered. They mainly address the source or technique used to achieve a misuse:

- NP1: external
- NP2: hardware misuse
- NP3: masquerading
- NP4: pest programs
- NP5: bypasses
- NP6: active misuse
- NP7: passive misuse
- NP8: inactive misuse
- NP9: indirect misuse

Lindqvist’s Extension

Lindqvist and Jonsson (1998) extended Neumann and Parker’s method by expanding categories NP5 (bypassing intended controls), NP6 (active misuse of resources), and NP7 (passive misuse of resources). They introduced the concept of dimension: attacks have certain intrusion techniques and certain intrusion results. Their extensions of Neumann and Parker’s categories NP5 to NP7, along with their intrusion techniques is given in Lindqvist and Jonsson (1997).

Jayaram and Morse’s Network Security Taxonomy

Jayaram and Morse (1997) developed a taxonomy of security threats to networks including five classes:

Physical: Security breach arising from the theft of components and systems, often perpetrated through impersonation.

System Weak Spots: Weak spots in operating systems or other system software that a perpetrator exploits for unauthorized access to the systems.

Malign Programs: A perpetrator embeds malevolent programs (viruses, for example) in a system with the intention of causing destruction to the information carried by the system.

Access Rights: Legitimate user’s identity usurped by “acquiring” user’s access rights through password traps, password cracking, etc. to gain illegitimate access to system resources.

Communication-based Network connectivity opens up opportunities for illegal information access through such means as eavesdropping, spoofing, etc.

NEED FOR ATTACK MODELS

Attack models are mainly needed to prevent the occurrence of threats, to react against network intrusions, or to perform a digital investigation after an intrusion has occurred. These models should particularly allow:

- Representing complex attacks by combining elementary attacks and addressing the dependencies that may be noticed between the actions engaged by a complex attack.
- Selecting the appropriate security decisions that prevent threats from occurring based on a decision-making process using various criteria.

- Identifying the reactions that make the system recover to its initial state after a security incident has occurred.
- Detecting the occurrence of harmful events by allowing the management of metrics monitoring system activity and reasoning about sensor performances.
- Proving evidence of harmful intrusions by tracing activities, marking activities, inspecting logs, storing appropriate events, and considering relations with legal issues.

Representing attacks against computer networks is among the most challenging tasks of the risk analyst. The representation should cope with the nature of the link between the actions composing an attack, the number of actions, and the size of the target systems. This stems from the intrinsic complexity of these attacks, which can be reduced to the following points:

1. A corresponding predictive model would be hard to evolve because network attacks are conducted by humans. Unlike most of the natural behaviors, human thoughts cannot be easily translated into a formal representation. Most of the existing methods assume the existence of an attack database without addressing this issue.
2. Attacks are seldom performed in a single step. Attackers often follow a structured method to achieve malicious acts. Hence, the risk analyst should establish various kinds of links between elementary threats (e.g., causality, time precedence). The major shortcoming of the traditional approaches is that they do not integrate security countermeasures and enterprise resources as a part of the expert knowledge related to attack scenarios.
3. Attacks belonging to the same scenario could be spatially and temporally distributed. Some attacks that constitute part of a scenario will not be represented in the alert stream. This could be due to missing sensor coverage or because the attack—albeit part of an attack scenario—is indistinguishable from normal benign activity.

Digital investigation is another challenging task that a security manager needs to face, since this manager's objectives are to gather evidence and analyze it to apprehend attackers. To build a strong link between the evidence and the attacker, the representation model should integrate enough knowledge of the applicable legal framework and the security policy enforced in the system to protect (Hamdi and Boudriga 2005, Security policy guidelines). Identification, for example, is a complex task to manage because of the huge volume of data that may need to be analyzed (Reith, Carr, and Gunch 2002).

Correlation handling is a third primary concern that network attack modeling should address. To be able to secure assets, effective detection is needed. Most existing models on intrusion detection focus on activities generated by a single source, which has resulted in many false positives and undetected attacks. Overcoming this requires correlating activities from all involved components

and analyzing logs together. This is because an intrusion typically leaves multiple signs of presence that are correlated somehow.

STRUCTURAL MODELS

A set of techniques modeling the structure of network attacks is presented in this section. The richness of each of these techniques is evaluated and some implementation issues are also investigated. Two major attack model categories—preventive models and reactive models—will be considered to address risk management, protection mechanisms, and effective response to intrusions.

Preventive Models

Modeling attacks before their occurrence is a crucial task because a priori information about an adversary's behavior is hard to obtain and because attacks are gaining in complexity and evolving tremendously. Particularly, the probability and the impact, which are among the most important attack attributes, cannot be precisely determined.

One of the most important issues is to model the gradual evolution of the attacker's plan to reach the main objective. It has been remarked that attackers often proceed through multiple steps in order to fulfill their malicious intentions. Tree structures have therefore been introduced to capture those steps. Indeed, fault trees, which have been used for a long time to analyze the failure conditions of complex systems, have been adapted to the computer network security context. Several risk-management approaches, such as CORAS (Stolen et al. 2003) rely on fault-tree analysis (FTA) to evaluate and prioritize risks. Two concepts have been especially focused: minimal cut sets and top event frequencies. The former identifies attack scenarios (or composite attacks) while the latter allows the computation of the frequency of the main attack with respect to the frequencies of the elementary threats. Helmer et al. (2006) also proposed using FTA to model attacks within the frame of an intrusion-detection approach.

Attack trees, which were first introduced by Schneier (2001) and extended by Tidwell et al. (2001), can be seen as a transposition of FTA into the computer security field. Their purpose is to determine and assess the possible sequences of events that would lead to the occurrence of a main attack. The root of a tree represents the main objective of an attacker while the subordinate nodes represent the elementary attacks necessary to perform in order to achieve the global goal. Writing a global threat as the conjunction of multiple threat scenarios offers a useful tool to the risk analyst, who can henceforth describe the various manners for achieving the main attack.

A substantial attack library has been proposed by Moore et al. (2001). This approach relies on attack patterns, which are essentially used to build generic representations of attack scenarios. The constituents of an attack pattern are mainly: (1) the goal of the attack, (2) a list of preconditions (i.e., hypotheses that should be verified by the system so that the attack succeeds), (3) the attack mechanism (i.e., the steps followed by the attacker to reach the objective), and (4) a list of postconditions (changes

to the system state resulting from the occurrence of the attack). Attack patterns are in turn organized into attack profiles that introduce variants (i.e., abstract parameters that can be instantiated with concrete values). Moreover, the approach develops the concept of attack tree refinement to enrich the library of a particular organization. Generic attack profiles are used to this purpose. If the analyzed system presents a set of values that match with several variants parameters, then the attack profile is said to be consistent with the system architecture. Then, the instantiation principle is applied to determine which attack pattern has the same goal as the identified attack. Based on this reasoning, three enriching mechanisms have been defined: (1) leaf-node application, (2) non-leaf-node application to OR-decomposition, and (3) non-leaf-node application to AND-decomposition.

McDermott (2000) has presented *Attack Net*, an attack modeling approach relying on Petri nets. A Petri net is customarily composed of places, transitions, arcs, and tokens. Places are the equivalent of graph nodes while a transition is a token move between two places. According to this analogy, attack steps are represented by places that are similar to nodes in attack trees. Basically, an attack net consists of a set of places and a set of transitions representing, respectively, the various states of the target system and the events that may trigger state changes. Moreover, tokens are used to evaluate the progression of a given attack through the study of a set of moves within the attack net. Attack nets combine the advantages of hypothetical flaws and attack trees. The main difference with these concepts is that attack events (i.e., transitions) are described separately from the system states (i.e., places). On the opposite side, attack trees merge the preconditions, the postconditions, and the running steps of a given attack into a single node. McDermott asserts that "Attack nets are better than attack trees for top-down testing of poorly documented operational systems." Furthermore, transitions can catch a vast variety of relationships between system states. As a passing remark, transitions turn out to be more efficient than AND/OR operators to build attack libraries. In fact, these traditional logical operators exhibit some important limits, especially when enriching an existing state. For instance, adding an AND branch to a set of alternatives (OR node) cannot be achieved without restructuring the child nodes.

Recently, more sophisticated models have been developed. In Steffan and Schumacher (2002), attack nets have been combined with the WikiWeb system to enable knowledge sharing. Moreover, Wiki pages can contain customized descriptions of the formal objects (i.e., places, transitions, tokens). This gives more flexibility with respect to the rigorous attack nets. Particularly, this allows building attack libraries through a collaborative process that involves many security experts. Of course, this means that managing attack libraries using this framework (called *AtiKi*) makes them richer.

Reactive Models

When reacting to a security incident, the attack damages may inadvertently increase. Stopping a machine or counterattacking the attack source may worsen the system

state. Hence, reactions should be selected according to a sound method. The most prominent criteria to model attacks in this context are given in the following:

Detection cost: Prior to the generation of a security alert by an analyzer, the corresponding sensor should have captured the required parameters appropriately (e.g., metric value, packet header fields). Then, the analyzer inspects these data to decide whether an intrusion occurred. Both of these operations have a cost that must be taken into account when computing the total cost of the incident. That cost is often supposed to be intrinsic to the elementary IDS components (consisting of an analyzer and a sensor); therefore, it does not depend on the nature of the generated alert.

Cost of reaction: Each of the potential reactions has a cost that depends heavily on the reaction itself. This cost can be expressed in terms of different attributes such as monetary units, processing resources, or time to repair.

Attack impact: Carrying out a malicious act on an information system causes various kinds of undesirable effects. To this purpose, the impact representing these effects should be represented by multiple attributes. Furthermore, a novel concept, called "progression factor," has been introduced in (Fessi et al. 2007) to have a more suitable representation of the benefit of a given reaction. In fact, the system can react before or after the attack occurs. Each of these reactions has a different benefit. The former aims at stopping the complete execution of the attack after receiving signals that reveal it, while the objective of the latter is to make the system recover at the right time.

IDS efficiency: Efficiency represents a fundamental topic in reactive attack modeling. It should detect a substantial percentage of intrusion into the supervised system while still keeping the false alarm rate at an acceptable level. In our case, it relies on two factors: the alert and the related attack.

TOWARD AN ATTACK-RESPONSE STRATEGY

The available security surveys show that a wide proportion of the enterprises that have been subjected to security incidents did possess, at the moment they were attacked, some security components. Hence, firewalls, intrusion-detection systems (IDSs), and antivirus programs, to name just a few, are not sufficient to attain an acceptable security level. Consistent strategies should be built for this purpose. In particular, we will point out three components that are often missed by security officers.

Security Policy

The need of an enterprise for a security policy (SP) can be driven by various reasons, which depend essentially on the organization's nature, the organization's business, and the context in which it operates. They can be divided into two major categories: business-oriented objectives and regulatory objectives (Hamdi and Boudriga 2005, Forensic computing).

Business-Oriented Objectives

The reasons beyond developing and implementing SPs should align with the basic organizational objectives. The benefits from having a SP can be either direct or indirect. Some can be easily assessed in monetary terms (e.g., preventing critical assets from being attacked) while the others are rather nonconcrete (e.g., preserving the reputation of the enterprise). The most important among the business-oriented objectives are:

- The measures of the SP should maintain the security of critical components at an acceptable level. In other terms, the SP helps enterprises in reducing the amount of risk related to harmful adverse events, and augment employee awareness.
- The SP must include some response schemes that make the system recover if an incident occurs (e.g., security attack, natural disaster). It also must develop appropriate procedures in conformance with the enforced law and the risks related to the organization's activity. Individual responsibilities and consequences must be defined in a SP.
- The SP must, whenever an incident occurs, ensure the continuity of the critical processes conducted by an enterprise. It should contain recovery plans and be accompanied by a set security guidelines to ensure efficient continuity and recovery.

Regulatory Objectives

The security measures of the SP are often developed as a regulatory obligation. Organizations that operate in sensitive sectors are particularly concerned with this issue. In the following, we will illustrate our reasoning by using two significant examples: banks and CAs (certification authorities). The former are accountable for the operations they carry out while the latter handle various types of critical information (e.g., key pairs, private user information). Among others, the following principles have to be respected:

- *Duty of loyalty*: When carrying her charges, an employee must place the employer's interest above her own. The relationship between the enterprise and the employee should be based on honesty and faith.
- *Conflict of interest*: A conflict of interest occurs in a situation in which the impact of a given action is positive for a category of employees and negative for others. The SP should guarantee that the security rules do not include such discriminatory clauses.
- *Duty of care*: The employees should proceed with caution when performing critical tasks. For example, the internal security auditing team should adequately protect the resources to which it has access (e.g., log files, personal information) to avoid divulging confidential information.
- *Accountability*: In order to be accounted for, employees should be uniquely identified and authenticated. When the responsibility of an employee has a legal aspect, which is often the case, the identification and authentication have to be compliant with the regulation. More precisely, credentials used for authentication purposes

must conform to legislation. For instance, when asymmetric cryptographic keys are of use in this context, SP developers should verify that protocols (e.g., generation protocols, encryption protocols), format, and key lengths do not conflict with the regulatory framework.

Monitoring

This monitoring task is often reduced to a continuous control of the system state and the collection of simple events that the system triggers when specific things occur. However, it seems inadvisable to confine monitoring to its pure security facets. It should provide for an efficient analysis of collected events, rapid generation of alerts, enhanced capability of learning, and incidence response. Incident response, for instance, should be enriched by a set of models allowing the accurate measurement of an incident's impact, and the selection of the appropriate reactions. At least three reasons confirm this idea:

- New vulnerabilities, exploits, and attack mechanisms can be discovered,
- Violations can be detected at the right time,
- Effective countermeasures can be reviewed to see whether they are as sufficient as they were thought to be at the design stage.

Security monitoring is customarily performed through the use of IDSs using two detection techniques: pattern-based monitoring and behavior-based monitoring. Pattern-based monitoring, also referred to as "misuse detection," attempts to characterize known patterns of security violations. This basically requires a sensor network, a signature database, and an analyzer. Sensors are deployed at the strategic segments of the monitored network to collect the needed data. Obviously, an engineering activity should be conducted before setting those sensors to ensure that the target information can be gathered without introducing a considerable overhead at the communication flow level (i.e., without affecting the quality of service). Signatures consist of descriptions of the known intrusions. An appropriate language is always needed for this representation. Finally, the analyzer matches the collected data with the existing signatures to decide whether an attack did occur. In addition to the description language, another important aspect that greatly affects the efficiency of pattern-based monitoring consists of identifying the parameters that should be controlled by the sensors. Because it is not possible to specify the behavior of the system with full confidence, the security analyst should define exactly what should be monitored. Among the most relevant issues that should be taken into account when defining attack signatures are the following:

Access to the information system objects: The access policy to the system assets (e.g., files, hosts) should be first expressed in a machine language. Then, the access events to critical resources should be logged and checked. For instance, in UNIX-based operating systems, the execution of the system command *ls* from a user account into */root/* directory should be detected. Moreover, the access policy corresponding to a malicious action can be specified.

A relevant example is to associate the existence of a Trojan horse to an open port.

Operations sequencing: The order in which some operations are executed is sometimes a good indicator of the legitimacy of an access. For example, the execution of some critical commands after being logged in as a normal user is prohibited. This shows how a signature can be based on a sequence of two, or more, events.

Protocol violation: Many signatures rely on detecting a communication flow that does not conform to the rules of a given protocol. For example, looking for IP packets in which the source and the destination addresses are the same permits the detection of a Land attack (which consists of sending a packet in which the source and destination IP addresses are identical). Likewise, checking the conformance of the fragmentation fields with the corresponding requests for comments (RFCs) allows thwarting fragmentation attacks such as Teardrop (which consists of sending two or more interleaving fragmented IP packets).

A behavior-based IDS, also referred to as an anomaly-based IDS, looks at actions, attempting to identify attacks by monitoring system or network activity and flagging any activity that does not seem to fit in. Anomaly detectors identify abnormal or unusual behavior (anomalies) on a host or network. They function on the assumption that attacks are different from “normal” (or legitimate) activity and can therefore be detected by systems that identify these differences. Anomaly detectors construct profiles representing normal behavior of users, hosts, or network connections. These profiles are constructed from historical data collected over a period of normal operation. The detectors then collect event data and use a variety of measures to determine when monitored activity deviates from the norm. The most used techniques in anomaly detection include:

Threshold detection, in which certain attributes of user and system behavior are expressed in terms of counts, with some level established as permissible. Such behavior attributes can include the number of files accessed by a user in a given period of time, the number of failed attempts to log in to the system, the amount of CPU space used by a process, etc. This level can be static or adaptive (i.e., designed to change with actual values observed over time).

Statistical measures—both parametric, in which the distribution of the profiled attributes is assumed to fit a particular pattern, and nonparametric, in which the distribution of the profiled attributes is “learned” from a set of historical values, observed over time.

Rule-based measures, which are similar to nonparametric statistical measures in that observed data define acceptable usage patterns, but differ in that those patterns are specified as rules, not numeric quantities.

Techniques belonging to the first class are categorized by two major shortcuts. First, they are not able to detect previously unknown attacks because it is often impossible to map them to any existing signature. Second, as different

manners can exist to carry out a specific attack, it might be difficult to build signatures that cover all the variants of such intrusions.

Anomaly detectors often produce a large number of false alarms, as normal patterns of user and system behavior can vary wildly. Despite this shortcoming, researchers assert that anomaly-based IDSs are able to detect new attack forms, unlike signature-based IDSs, which rely on matching patterns of past attacks. Furthermore, some forms of anomaly detection produce output that can in turn be used as information sources for misuse detectors. For example, a threshold-based anomaly detector can generate a figure representing the “normal” number of files accessed by a particular user; the misuse detector can use this figure as part of a detection signature that says “if the number of files accessed by this user exceeds this “normal” figure by ten percent, trigger an alarm.”

A significant problem with security-incident detection and response systems is the high number of false alarms. Various techniques are therefore developed to assist the security manager in understanding security faults and attacks. Visualization is perhaps the most renowned monitoring-assistance approach. It can be defined as a translation of the abstract data generated by the IDS to a visual interactive data set. Generally, the visualization process consists of three steps:

1. **Data transformation:** Consists of mapping raw data generated by the detection system to structured data, called “data tables.” This can range from relational description techniques to metadata extraction,
2. **Visual mapping:** Extracts visual structures of the data tables based on spatial substrates, marks, and graphical properties,
3. **Visual transformation:** Allows building views by fixing graphical parameters (e.g., position, scaling, clipping).

The reader can find more information about these tasks in Axelsson (2004).

Another important aspect of security state monitoring is the use of honeypots, which are traps set to detect and trace attack-related activities. Honeypots also provide a useful tool to build accurate statistics about specific threats. Traditionally, they consist of isolated subnetworks that are seemingly important and sensitive. Therefore, they constitute good targets for malicious users. However, they are appropriately protected so that the attack damage is confined to the isolated perimeter. Honeypots have also been used to benchmark several detection mechanisms as in the DARPA-MIT Lincoln IDS evaluation project (www.ll.mit.edu/IST/ideval/index.html).

Incident Response

Accurate and fast response to attacks should be implemented. This process is hard to put in place because it is a hybrid, in the sense that it involves both human and automated reasoning. It is worth mentioning that the response strategy should be built based on the attacks that threaten the target system.

When an incident has been detected and analyzed, it is important to contain it before the spread of the incident

overwhelms resources or the damage increases. Most incidents require containment, so it is important to consider it early in the course of handling each incident. An essential part of containment is decision making (e.g., shut down a system, disconnect it from a wired or wireless network, disconnect its modem cable, disable certain functions). Such decisions are much easier to make if strategies and procedures for containing the incident have been predetermined.

Another key task related to the incident-response process is evidence gathering and source tracing. Although the primary reason for gathering evidence during an incident is to resolve the incident, it may also be needed for legal proceedings. In such cases, it is important to clearly document how all evidence, including compromised systems, has been preserved. Evidence should be collected according to procedures that meet all applicable laws and regulations, developed from previous discussions with legal staff and appropriate law-enforcement agencies, so that it would be admissible in court. In addition, evidence should be accounted for at all times; whenever evidence is transferred from person to person, chain of custody forms should detail the transfer and include each party's signature. A detailed log should be kept for all evidence, including the following:

Identifying information (e.g., the location, serial number, model number, hostname, media access control (MAC) address, IP address of a computer)

Name, title, and phone number of each individual who collected or handled the evidence during the investigation

Time and date (including time zone) of each occurrence of evidence handling

Locations where the evidence was stored

Multiple techniques have been proposed by Casey (2001) to identify an attacker. Identifying the attacker can be a time-consuming and futile process that can prevent a team from achieving its primary goal—minimizing the business impact. The following items describe the most commonly performed activities for attacker identification:

Validating the Attacker's IP Address

New incident handlers often focus on the attacker's IP address. The handler may attempt to validate that the address was not spoofed by using pings, traceroutes, or other methods of verifying connectivity. However, this is not helpful because at best it indicates that a host at that address responds to the requests. A failure to respond does not mean the address is not real—for example, a host may be configured to ignore pings and traceroutes. The attacker may have received a dynamic address (e.g., from a dial-up modem pool) that has already been reassigned to someone else. More importantly, if the IP address is real and the team pings it, the attacker may be tipped off that the organization has detected the activity. If this occurs before the incident has been fully contained, the attacker could cause additional damage, such as wiping out hard drives that contain evidence of the attack. The team should consider acquiring and using IP addresses from another organization (e.g., an ISP) when performing actions such

as address validation so that the true origin of the activity is concealed from the attacker.

Scanning the Attacker's System

Some incident handlers do more than perform pings and traceroutes to check an attacking IP address. They may run port scanners, vulnerability scanners, and other tools to attempt to gather more information on the attacker. For example, the scans may indicate that Trojan horses are listening on the system, implying that the attacking host itself has been compromised. Incident handlers should discuss this issue with legal representatives before performing such scans because the scans may violate organization policies or even break the law.

Researching the Attacker through Search Engines

In most attacks, incident handlers may have at least a few pieces of data regarding the possible identity of the attacker, such as a source IP address, an e-mail address, or an IRC nickname. Performing an Internet search using these data may lead to more information on the attacker—for example, a mailing list message regarding a similar attack, or even the attacker's Web site. Research such as this generally does not need to be performed before the incident has been fully contained.

Using Incident Databases

Several groups collect and consolidate intrusion detection and firewall log data from various organizations into incident databases. Some of these databases allow people to search for records corresponding to a particular IP address. Incident handlers could use the databases to see if other organizations are reporting suspicious activity from the same source. The organization can also check its own incident-tracking system or database for related activity.

Monitoring Possible Attacker Communication Channels

Another method that some incident handlers use to identify an attacker is to monitor communication channels that may be used by an attacker. For example, the attacker may congregate on certain IRC channels to brag about Web sites that they have defaced. However, incident handlers should treat any such information that they acquire only as a potential lead to be further investigated and verified, not as fact.

COUNTERMEASURE-SELECTION GUIDELINES

Practical measures (security solutions) are given in this section to maintain the protected system at an acceptable security level. These solutions will be either preventive or reactive. They can be implemented at the different vulnerable points of the system. Mainly, the security of the assets listed below will be addressed:

- Desktop workstations
- Public and private servers
- Storage and archival servers
- Wireless LANs

Among others, the countermeasures presented in these guidelines will allow:

The secure configuration of the crucial assets
 The accurate and fast detection of harmful events
 The efficient response to the detected incidents
 The precise identification of attack sources

Most of the proposed guidelines have appeared in the CERT security guidelines series.

Desktop Workstation Security

Security of a desktop workstation is mainly the responsibility of users. Their daily work usually requires that protected information resources be accessed, manipulated, modified, and transmitted across networks. However, it also requires considerable planning activity at the management level. The following points (Allen 2001) highlight the most important actions that should be implemented to secure workstations:

- Develop a computer deployment plan that includes security issues.
- Keep operating systems and applications software up to date.
- Configure computers for user authentication.
- Configure computer operating systems with appropriate object, device, and file access controls.
- Identify data that characterize systems and aid in detecting signs of suspicious behavior.
- Manage logging and other data-collection mechanisms.
- Configure computers for file backups.
- Protect computers from viruses and similar programmed threats.
- Configure computers for secure remote administration.
- Configure computers to provide only selected network services.
- Configure network service clients to enhance security.
- Configure multiple computers using a tested model configuration and a secure replication procedure.
- Allow only appropriate physical access to computers.

Public and Private Server Security

Public servers require special attention when being protected because their security needs differ from normal network nodes. The following actions (Allen 2001) represent the core of a set of recommended practices allowing securing public servers:

- Isolate the server from public networks and your organizations internal networks.
- Configure the server with appropriate object, device, and file-access controls.
- Identify and enable server-specific logging mechanisms.
- Consider security implications before selecting programs, scripts, and plug-ins for the public server.

- Configure the server to minimize the functionality of programs, scripts, and plug-ins.
- Configure the server to use authentication and encryption technologies, where required.
- Maintain the authoritative copy of your site content on a secure host.
- Protect the public server against common attacks.

Storage and Archival Server Security

Because of their focal role, it is common for servers to store many of an organization's most valuable and confidential information resources. They also are often deployed to provide a centralized capability for an entire organization, such as communication (e-mail) or user authentication. Security breaches on a network server can result in the disclosure of critical information or the loss of a capability that can affect the entire organization (Rekhis, Boudriga, and Obaidat 2005). Therefore, securing network servers should be a significant part of the organization's network and information security strategy. Several important guidelines for storage and archival servers are given below (Allen 2001):

- Develop a computer deployment plan that includes security issues.
- Include explicit security requirements when selecting servers.
- Keep operating systems and applications software up to date.
- Offer only essential network services and operating system services on the server host machine.
- Configure computers for user authentication.
- Configure computer operating systems with appropriate object, device, and file access controls.
- Identify data that characterize systems and aid in detecting signs of suspicious behavior.
- Manage logging and other data-collection mechanisms.
- Configure computers for file backups.
- Protect computers from viruses and similar programmed threats.
- Configure computers for secure remote administration.
- Allow only appropriate physical access to computers.

Wireless LAN Security

Wireless LANs (WLANs) are inherently less secure than wired networks because:

The signal is broadcast, the network is shared, and any network device can listen to network traffic for any other network device in range, making privacy and authentication difficult

The signal spreads outside buildings, so physical security is ineffective and it could be very difficult to locate a rogue device

Mistakes were made in designing wireless network standards so that the built in WEP (wired equivalent privacy) is effectively useless—it gives no assurance of privacy;

Efficient operation of wireless networks depends on a planned approach to the allocation of the limited spectrum available in the 2.4-GHz band and rogue wireless equipment may interfere with and degrade the performance of authorized services.

There are different alternatives for securing a connection: end-to-end security at the application level, end-to-end security at the transport layer and link security at the link layer. Several useful protection techniques for wireless networks are listed in the following:

Authentication: An authentication method for wireless networks has to be mutual, self-protecting, and immune to dictionary attacks. This means that it must: (1) provide mutual authentication—that is, the authenticator must authenticate the user, but the user must be able to authenticate the authenticator as well; (2) protect itself from eavesdropping since the physical medium is not secure; and (3) be robust against online or offline dictionary attacks. An online attack is one in which the imposter must make repeated tries against the authenticator “online.” These can be thwarted by limiting the number of failed authentication attempts a user can have. An offline attack is one in which attackers can make repeated tries on their own computers, very rapidly, and without the knowledge of the authenticator. Simple challenge/response methods are susceptible to offline attacks because if attackers capture a single challenge/response pair, they can try all the passwords in the dictionary to see if one produces the desired response.

Encryption: Encryption software can be used to protect the confidentiality of sensitive information stored on handheld devices and mirrored on the desktop PC. The information on add-on backup storage modules should also be encrypted and the modules securely stored when not in use. This additional level of security can be added to provide an extra layer of defense to further protect sensitive information stored on handheld devices. Many software programs are freely available to help users encrypt these types of files for an added layer of security.

Antivirus software: Malicious codes are often used to compromise handheld devices. Antivirus software should therefore be used to scan the content of the mobile devices and to remove harmful components.

Public Key Infrastructures: Using certified asymmetric keys to protect networks is among the most secure techniques. A certification authority is needed to achieve this task. A regulatory framework should also be available to set the dues of the different parties participating in the wireless electronic transactions. Wireless public key infrastructure (PKI) should take into account the mobility of the handled devices.

VPNs: A VPN creates a virtual private network between the handheld device and the organization’s network by sharing the public network infrastructure. VPN technology offers the security of a private network through access control and encryption, while taking advantage of the economies of scale and built-in management facilities of large public networks. This technique is widely used in wired networks and is being extended to wireless

networks. A VPN can be used to authenticate access points at the network and link layers, and to encrypt the packets exchanged between handled devices.

MAJOR CHALLENGES

This section covers the most important challenges that are currently faced by the security community. Three main aspects are underlined:

Need for new response methods: Decision making to thwart security attacks is guided by many requirements (e.g., cost-effectiveness, real-time). Therefore, new security structures and processes are needed. Structured libraries seem to be an accurate choice to address this need. They allow to: (1) share the knowledge of security experts, (2) reuse security countermeasures that were implemented in the past, when similar security challenges are faced, and (3) make useful security-related information available for different user categories.

Secure protocol design: Most of the attacks discussed in the section on “Analyzing the Attacker’s Objectives” are due to several weaknesses characterizing most of the network protocols. This emphasizes the need for integrating security at the earliest phases of protocol design. To this end, risk-analysis step, allowing the selection of the most efficient security solutions, should be conducted.

Quality of Service (QoS) versus security: Setting the QoS requirements for an application involving computing and communication infrastructures may turn out to conflict with the security objectives. Effectively, the application of strong security policies often induces delays and overhead. This renders QoS requirements hard to satisfy.

Attacks against new-generation networks: Mobility, which is among the most important characteristics of the new-generation networks, has introduced some novel topologies, in which some critical (from security point of view) tasks can be delegated by operators to normal users. This introduces some important security concerns that should be considered.

GLOSSARY

Alert: An alert is an attack description that is achieved by monitoring several system parameters. It provides the capability to detect and identify the potential intrusions that are carried out on the victim assets.

Attack: An attack is an action conducted in order to harm a networked system. Attackers’ objectives vary from disrupting a vital service to accessing private information.

Firewall: Network firewalls are devices or systems that control the flow of network traffic between networks using differing security postures. In most modern applications, firewalls and firewall environments are discussed in the context of Internet connectivity and the TCP/IP suite. Firewalls are typically categorized into a few types: packet filters, stateful inspection firewalls, and application proxies.

Incident Response: A process involving the actions that should be executed to limit the impact of an attack that has occurred. Time and cost-benefit are the most important parameters involved in this process.

Intrusion: Any activity that violates the security policy can be qualified as an intrusion. Hence, an attack does not necessarily correspond to an intrusion. In fact, because of some lacks at the security policy level, several attacks cannot be mapped to intrusion schemes.

Intrusion-Detection System (IDS): Software or hardware systems that automate the process of monitoring the events occurring in a computer system or network, analyzing them for signs of security problems.

Security Policy: A set of rules that define how critical assets should be secured within a networked system.

System Monitoring: Monitoring consists of performing a continuous control of the system's security state. It allows detecting new vulnerabilities, detecting security policy violations, and reacting in a convenient manner.

Threat: Any event that can result in a loss for a sensitive system. It can be malevolent, accidental, or even due to natural disaster. A threat is generally characterized by a probability of occurrence and an outcome.

Virus: A program or piece of code that is introduced into a computer and runs against the security policy. Viruses have the ability to replicate themselves, they are therefore dangerous because they can use all available disk and memory resources, bringing the system to a halt.

Worm: A program or algorithm that replicates itself over a computer network and usually performs malicious actions. A worm is generally characterized by a payload defining the malicious action(s) that it can perform.

INTRODUCTION

Computer viruses are unique among the many security problems because the fact that someone else is infected increases the risk to you. However, viruses also seem to be surrounded by myths and misunderstandings. In this chapter we will help to set the record straight.

History of Computer Viruses and Worms

Many claims have been made for the existence of viruses prior to the 1980s, but so far these claims have not been accompanied by proof. The Core Wars programming contests, frequently cited as early examples of virus-like computer programs, did involve self-replicating code, but usually within a structured and artificial environment. Primarily on the basis of a "copyright" date of 1986 included in the code of the Brain virus, 2006 has been hailed as the 20th anniversary of computer viruses.

The general perception of computer viruses, even among security professionals, has concentrated on their existence in personal computers, and particularly "Wintel"-type systems. This is despite the fact that Fred Cohen's (1984) seminal academic work took place on mainframe and minicomputers in the mid-1980s. The first e-mail virus was spread in 1987. The first virus hoax message (then termed a "metavirus") was proposed in 1988. Even so, virus and malware research has been neglected, possibly because malware does not fit easily into the traditional access-control security models.

At least two Apple II viruses are known to have been created in the early 1980s. However, it was not until the end of the decade (and 1987 in particular) that knowledge of real viruses became widespread, even among security

experts. For many years boot-sector infectors and file infectors were the only types of common viruses. These programs spread relatively slowly, primarily distributed on floppy disks, and were thus slow to disseminate geographically. However, these viruses tended to be very long lived.

During the early 1990s virus writers started experimenting with various functions intended to defeat detection. (Some forms had seen limited trials earlier.) Among these were polymorphism (to change form in order to defeat scanners) and stealth (to attempt to confound any type of detection). None of these virus technologies had a significant impact. Most viruses using these "advanced" technologies were easier to detect because of a necessary increase in program size. (Although various detection-avoidance technologies may make detection of viruses difficult, and possibly computationally expensive, it is impossible to make a virus that cannot be detected by some means. At the same time, Fred Cohen's work, noted later in this article, has proven that a "perfect" antivirus, which can detect all possible viruses without ever making an error, is not going to happen. Therefore, we are faced with a situation in which we cannot know, with complete assurance, that all viruses have been found, but we likewise know that no virus can reliably evade detection.)

Although demonstration programs had been created earlier, the mid-1990s saw the introduction of macro and script viruses in the wild. These were initially confined to word-processing files, particularly files associated with the Microsoft Office Suite. However, the inclusion of programming capabilities in office productivity applications eventually led to macro and script viruses in many objects that would normally be considered to contain data only,

such as Excel spreadsheets, PowerPoint presentation files, and e-mail messages. This fact led to greatly increased demands for computer resources among antiviral systems, since many more objects had to be tested, and Windows OLE (object linking and embedding) format data files presented substantial complexity to scanners. Macro viruses also increase new variant forms very quickly, since the virus carries its own source code, and anyone who obtains a copy can generally modify it and create a new member of the virus family.

E-mail viruses became the major new form in the late 1990s and early 2000s. These viruses may use macro capabilities, scripting, or executable attachments to create e-mail messages or attachments send out to e-mail addresses harvested from the infected machine. E-mail viruses spread extremely rapidly, distributing themselves worldwide in a matter of hours. Some versions create so many copies of themselves that corporate and even service provider mail servers become flooded and cease to function. E-mail viruses are very visible, and so tend to be identified within a short time, but many are macros or scripts, and so generate many variants.

With the strong integration of the Microsoft Windows operating system with its Internet Explorer browser, Outlook mailer, Office suite, and system scripting, recent viruses have started to blur the normal distinctions. A document sent as an e-mail file attachment can make a call to a Web site that starts active content that installs a remote-access tool acting as a portal for the client portion of a distributed denial-of-service network. Indeed, not only are viruses starting to show characteristics that are similar to each other, but functions from completely different types of malware are beginning to be found together in the same programs, leading to a type of malware convergence.

Many security specialists have stated that the virus threat is decreasing, since, despite the total number of virus infections being seen, the prevalent viruses are now almost universally e-mail viruses, and therefore constitute a single threat with a single fix. This ignores the fact that, although almost all major viruses now use e-mail as a distribution and reproduction mechanism, there are a great many variations in the way e-mail is used. For example, many viruses use Microsoft Outlook mailer to spread, and reproduction can be prevented simply by removing Outlook from the system. However, other viruses may make direct calls to the mail application programming interface (MAPI), which is used by a number of mail-user programs, while others carry the code for mail server functions within their own body. A number of e-mail viruses distribute themselves to e-mail addresses found in the Microsoft Outlook address book files, while others may harvest addresses from anywhere on the computer hard drive, or may actually take control of the Internet network connection and collect contact data from any source viewed online.

Because virus research has had to deal with detailed analysis of low-level code, it has led to significant advances in the field of forensic programming. However, to date computer forensic work has concentrated on file recovery and decryption, so the contributions in this area likely still lie in the future.

With regard to current threat levels, a 2005 FBI computer crime survey (authored by Special Agent Bruce Verduyn and publicly posted on the Web, but no longer available on the Web at the time of writing) noted that not only were malware attacks the largest single class of computer crimes, but they were responsible for fully one-third of the financial damage resulting from all computer crime. According to the figures collected in the report, in 2004/2005, malware attacks resulted in an estimated loss of six million dollars per hour in the United States alone. According to many other reports and studies, the threat continues to grow.

Many computer pundits, as well as some security experts, have proposed that computer viruses are a result of the fact that currently popular desktop operating systems have only nominal security provisions. They further suggest that viruses will disappear as security functions are added to operating systems. This thesis ignores the fact, well established by Cohen's research and subsequently confirmed, that viruses use the most basic of computer functions, and that a perfect defense against viruses is impossible. This is not to say that an increase in security measures by operating-system vendors could not reduce the risk of viruses: the current danger could be drastically reduced with relatively minor modifications to system functions.

It is going too far to say (as some have) that the very existence of virus programs, and the fact that both viral strains and the numbers of individual infections are growing, means that computers are finished. At the present time, the general public is not well informed about the virus threat, and so more copies of virus programs are being produced than are being destroyed.

Indeed, no less an authority than Fred Cohen has championed the idea that virus programs can be used to great effect. An application using a viral form can improve performance in the same way that computer hardware benefits from parallel processors. It is, however, unlikely that virus programs can operate effectively and usefully in the current computer environment without substantial protective measures being built into them. A number of virus and worm programs have been written with the obvious intent of proving that viruses could carry a useful payload, and some have even had a payload that could be said to enhance security. Unfortunately, all such viruses have created serious problems themselves.

Virus Definition

A computer virus is a program written with functions and intent to copy and disperse itself without the knowledge and cooperation of the owner or user of the computer. A final definition has not yet been agreed on by all researchers. A common definition is, "a program that modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen from his seminal research in the mid-1980s, although Dr. Cohen's actual definition is in mathematical form. Another possible definition is "an entity that uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action."

Cohen is generally held to have defined the term *computer virus* in his thesis (published in 1984). (The

suggestion for the use of the term virus is credited to Len Adleman, his seminar advisor.) However, his original definition covers only those sections of code that, when active, attach themselves to other programs. This, however, neglects many of the programs that have been most successful “in the wild”.

Many researchers still insist on Cohen’s definition and use other terms such as “worm” and “bacterium” for virus programs that do not attack other programs. Currently, viruses are generally held to attach themselves to some object, although the object may be a program, disk, document, e-mail message, computer system, or other information entity.

Computer virus programs are not a “natural” occurrence. Viruses are programs written by programmers. They do not just appear through some kind of electronic evolution—they are written, deliberately, by people. However, the definition of “program” may include many items not normally thought of in terms of programming, such as disk boot sectors, and Microsoft Office documents or data files that also contain macro programming.

Many people have the impression that anything that goes wrong with a computer is caused by a virus. From hardware failures to errors in use, everything is blamed on a virus. A virus is not just any damaging condition. Similarly, it is now popularly believed that any program that may do damage to your data or your access to computing resources is a virus. Virus programs are not simply programs that do damage. Indeed, virus programs are not always damaging, at least not in the sense of being deliberately designed to erase data or disrupt operations. Most virus programs seem to have been designed to be a kind of electronic graffiti: intended to make the writer’s mark in the world, if not with his or her name. In some cases a name is displayed, on occasion an address, phone number, company name, or political party.

Is My Computer Infected? What Should I Do?

In many books and articles you will find lists of symptoms to watch for in order to determine whether your computer is infected. These signs include things like running out of memory space, running out of disk space, the computer operating more slowly than normal, files changing size, and so forth. In fact, many factors will create these same effects, and current viruses seldom do. The best way to determine whether your computer has been infected by a virus is to get and use an antivirus scanner. In fact, get more than one. With the rapid generation of new viruses these days, it is quite possible for a maker of antivirus software to make mistakes in updating signatures. Therefore, having a second check on a suspected virus is always a good idea.

One scanner for the Wintel platform is F-PROT. It is available in a DOS version, free of charge from www.f-secure.com. (Look under “Downloads” and “Tools.”) Although a DOS scanner has some limitations in a Windows environment (particularly with an NTFS [new technology file system] in Windows XP), it will still be able to identify infected files, and is quite good at picking out virus

infections within e-mail system files (the files of messages held on your computer).

Another scanner available free is AVG (antivirus Grisoft), from www.grisoft.com. This one also does a good job of scanning, and will even update itself automatically (although that feature is problematic on some machines).

The various commercial antivirus program producers generally release trial versions of their software, usually limited in some way. Sophos and Avast have been very good in this regard.

Considering the suggestion to use more than one scanner, it should be noted that a number of successful software publishers have included functions that conflict with software from other vendors. These products should be avoided, because of the previously noted possibility of failure in a single protection program. The use of “free” software, and purchase of software from companies that provide such free versions, is recommended, since the existence of these free scanners, and their use by other people, actually reduces your risk, since there will be fewer instances of viruses reproducing and trying to spread. (In this situation I am speaking of software for which no fee is charged, rather than specifically open source “free” software.)

Readers may be surprised at the recommendation to use software that is free of charge: there is a general assumption that commercial software must be superior to that provided free. It should be noted that I am a specialist in the evaluation of security and, particularly, antivirus software, and I have published more reviews of antivirus software than any other individual. The reader can be assured that it can be proven that, in the case of antivirus software, free software is as effective, and in some cases superior to, many very expensive products.

TROJAN HORSES, VIRUSES, WORMS, RATs, AND OTHER BEASTS

Malware is a relatively new term in the security field. It was created to address the need to discuss software or programs that are intentionally designed to include functions for penetrating a system, breaking security policies, or carrying malicious or damaging payloads. Since this type of software has started to develop a bewildering variety of forms—such as backdoors, data diddlers, DDoS (distributed denial of service), hoax warnings, logic bombs, pranks, RATs (remote-access Trojans), Trojans, viruses, worms, zombies, etc.—the term has come to be used for the collective class of *malicious software*. The term is, however, often used very loosely simply as a synonym for virus, in the same way that virus is often used simply as a description of any type of computer problem. I will attempt to define the virus and worm problem more accurately, and to do this I need to describe the various other types of malware.

Viruses are the largest class of malware, both in terms of numbers of known entities, and in impact in the current computing environment. Viruses, therefore, tend to be synonymous, in the public mind, with all forms of malware. Programming bugs or errors are generally not

included in the definition of malware, although it is sometimes difficult to make a hard and fast distinction between malware and bugs. For example, if a programmer left a buffer overflow in a system and it creates a loophole that can be used as a backdoor or a maintenance hook, did he do it deliberately? This question cannot be answered technically, although we might be able to guess at it, given the relative ease of use of a given vulnerability.

In addition, it should be noted that malware is not just a collection of utilities for the attacker. Once launched, malware can continue an attack without reference to the author or user, and in some cases will expand the attack to other systems. There is a qualitative difference between malware and the attack tools, kits, or scripts, that have to operate under an attacker's control, and which are not considered to fall within the definition of malware. There are gray areas in this aspect as well, since RATs and DDoS zombies provide unattended access to systems, but need to be commanded in order to deliver a payload.

Trojans

Trojans, or Trojan horse programs, are the largest class of malware in terms of numbers of different entities produced. However, the term is subject to much confusion, particularly in relation to computer viruses.

A Trojan is a program that pretends to do one thing while performing another, unwanted action. The extent of the "pretense" may vary greatly. Many of the early PC Trojans relied merely on the filename and a description on a bulletin board. Log-in Trojans, popular among university student mainframe users, mimicked the screen display and the prompts of the normal log-in program and could, in fact, pass the username and password along to the valid log-in program at the same time as they stole the user data. Some Trojans may contain actual code that does what it is supposed to be doing while performing additional nasty acts that it does not tell you about.

Another confusion with viruses involves Trojan horse programs that may be spread by e-mail. In years past, a Trojan program had to be posted on an electronic bulletin board system or a file archive site. Because of the static posting, a malicious program would soon be identified and eliminated. More recently, Trojan programs have been distributed by mass e-mail campaigns, by posting on Usenet newsgroup discussion groups, or through automated distribution agents (bots) on Internet relay chat (IRC) channels. Since source identification in these communications channels can be easily hidden, Trojan programs can be redistributed in a number of disguises, and specific identification of a malicious program has become much more difficult.

Some data security writers consider that a virus is simply a specific example of the class of Trojan horse programs. There is some validity to this classification, since a virus is an unknown quantity that is hidden and transmitted along with a legitimate disk or program, and any program can be turned into a Trojan by infecting it with a virus. However, the term *virus* more properly refers to the added, infectious code rather than the virus/target combination. Therefore, the term *Trojan* refers to a deliberately misleading or modified program that does not reproduce itself.

A major aspect of Trojan design is the social engineering (fraudulent or deceptive) component. Trojan programs are advertised (in some sense) as having a positive component. The term *positive* can be disputed, since a great many Trojans promise pornography or access to pornography, and this still seems to be depressingly effective.

However, other promises can be made as well. A recent e-mail virus, in generating its messages, carried a list of a huge variety of subject lines, promising pornography, humor, virus information, an antivirus program, and information about abuse of the recipient's email account.

Sometimes the message is simply vague, and relies on curiosity. Social engineering really is nothing more than a fancy name for the type of fraud and confidence games that have existed since snakes started selling apples. Security types tend to prefer a more academic-sounding definition, such as the use of nontechnical means to circumvent security policies and procedures. Social engineering can range from simple lying (such as a false description of the function of a file), to bullying and intimidation (in order to pressure a low-level employee into disclosing information), to association with a trusted source (such as the username from an infected machine).

Worms

A worm reproduces and spreads, like a virus, and unlike other forms of malware. Worms are distinct from viruses, though they may have similar results. Most simply, a worm may be thought of as a virus with the capacity to propagate independently of user action. In other words, they do not rely on (usually) human-initiated transfer of data between systems for propagation, but instead spread across networks of their own accord, primarily by exploiting known vulnerabilities (such as buffer overflows) in common software.

Originally, the distinction was made that worms used networks and communications links to spread, and that a worm, unlike a virus, did not directly attach to an executable file. In early research into computer viruses, the terms *worm* and *virus* tended to be used synonymously, it being felt that the technical distinction was unimportant to most users. The technical origin of the term *worm program* matched that of modern distributed processing experiments: a program with "segments" working on different computers, all communicating over a network (Shoch and Hupp 1982).

The first worm to garner significant attention was the Internet Worm of 1988, discussed in detail in the section on "Worms (First and Third Generation)." Recently, many of the most prolific virus infections have not been strictly viruses, but have used a combination of viral and worm techniques to spread more rapidly and effectively. LoveLetter was an example of this convergence of reproductive technologies. Although infected e-mail attachments were perhaps the most widely publicized vector of infection, LoveLetter also spread by actively scanning attached network drives, infecting a variety of common file types. This convergence of technologies will be an increasing problem in the future. Code Red and a number of Linux programs (such as Lion) are modern examples of worms. (Nimda is an example of a worm, but it also

spreads in a number of other ways, so it could be considered to be an e-mail virus and multipartite as well.)

Viruses

A virus is defined by its ability to reproduce and spread. A virus is not just anything that goes wrong with a computer, and *virus* is not simply another name for *malware*. Trojan horse programs and logic bombs do not reproduce themselves.

A worm, which is sometimes seen as a specialized type of virus, is currently distinguished from a virus since a virus generally requires an action on the part of the user to trigger or aid reproduction and spread. The action on the part of the user is generally a common function, and the user usually does not realize the danger of the action, or the fact that he or she is assisting the virus.

The only requirement that defines a program as a virus is that it reproduces. It is not necessary that the virus carry a payload, although a number of viruses do. In many cases (in most cases of “successful” viruses), the payload is limited to some kind of message. A deliberately damaging payload, such as erasure of the disk, or system files, usually restricts the ability of the virus to spread, since the virus uses the resources of the host system. In some cases, a virus may carry a logic bomb or time bomb that triggers a damaging payload on a certain date or under a specific, often delayed, condition.

Because a virus spreads and uses the resources of the host, it affords a kind of power to software that parallel processors provide to hardware. Therefore, some have theorized that viral programs could be used for beneficial purposes, similar to the experiments in distributed processing that are testing the limits of cryptographic strength. (Various types of network-management functions, and updating of system software, are seen as candidates.) However, the fact that viruses change systems and applications is seen as problematic in its own right. Many viruses that carry no overtly damaging payload still create problems with systems. A number of virus and worm programs have been written with the obvious intent of proving that viruses could carry a useful payload, and some have even had a payload that could be said to enhance security. Unfortunately, all such viruses have created serious problems themselves. The difficulties of controlling virus programs have been addressed in theory, but the solutions are also known to have faults and loopholes.

Logic Bombs

Logic bombs are software modules set up to run in a quiescent state, but to monitor for a specific condition, or set of conditions, and to activate their payload under those conditions. A logic bomb is generally implanted in or coded as part of an application under development or maintenance. Unlike a RAT or Trojan it is difficult to implant a logic bomb after the fact. There are numerous examples of this type of activity, usually based on actions taken by a programmer to deprive a company of needed resources if the programmer’s employment is terminated.

A Trojan or a virus may contain a logic bomb as part of the payload. A logic bomb involves no reproduction, no social engineering. A persistent legend with regard to logic bombs involves what is known as the salami scam.

According to the story, this involves the siphoning off of small amounts on money (in some versions, fractions of a cent) credited to the account of the programmer, over a very large number of transactions. Despite the fact that these stories appear in a number of computer security texts, the author has a standing challenge to anyone to come up with a documented case of such a scam. Over a period of eight years, the closest anyone has come is a story about a fast-food clerk who diddled the display on a drive through window, and collected an extra dime or quarter from most customers.

Other Related Terms

Hoax virus warnings or alerts have an odd double relation to viruses. First, hoaxes are usually warnings about “new” viruses: new viruses that do not, of course, exist. Second, hoaxes generally carry a directive to the user to forward the warning to all addresses available to them. Thus, these descendants of chain letters form a kind of self-perpetuating spam.

Hoaxes use an odd kind of social engineering, relying on people’s naturally gregarious nature and desire to communicate, and on a sense of urgency and importance, using the ambition that people have to be the first to provide important new information. Hoaxes do, however, have common characteristics that can be used to determine whether their warnings may or may not be valid:

- Hoaxes generally ask the reader to forward the message.
- Hoaxes make reference to false authorities such as Microsoft, AOL, IBM, and the FCC (none of which issue virus alerts) or to completely false entities.
- Hoaxes do not give specific information about the individual or office responsible for analyzing the virus or issuing the alert.
- Hoaxes generally state that the new virus is unknown to authorities or researchers.
- Hoaxes often state that there is no means of detecting or removing the virus; many of the original hoax warnings stated only that you should not open a message with a certain phrase in the subject line. (The warning, of course, usually contained that phrase in the subject line. Subject-line filtering is known to be a very poor method of detecting malware.)
- Hoaxes often state that the virus does tremendous damage, and is incredibly virulent.
- Hoax warnings very often contain A LOT OF CAPITAL LETTER SHOUTING AND EXCLAMATION MARKS!!!!!!!!!!
- Hoaxes often contain technical sounding nonsense (technobabble), such as references to nonexistent technologies like “*n*th complexity binary loops.”

It is wise, in the current environment, to doubt all virus warnings, unless they come from a known and historically accurate source, such as a vendor with a proven record of providing reliable and accurate virus alert information, or preferably an independent researcher or group. It is best to check any warnings received against known virus encyclopedia sites. It is best to check more than one such

site: in the initial phases of a “fast burner” attack some sites may not have had time to analyze samples to their own satisfaction, and the better sites will not post information they are not sure about.

Remote-access Trojans (RATs) are programs designed to be installed, usually remotely, after systems are installed and working (and not in development, as is the case with logic bombs and backdoors). Their authors would generally like to have the programs referred to as remote administration tools, in order to convey a sense of legitimacy.

When a RAT program has been run on a computer, it will install itself in such a way as to be active every time the computer is started subsequent to the installation. Information is sent back to the controlling computer (sometimes via an anonymous channel such as IRC) noting that the system is active. The user of the command computer is now able to explore the target, escalate access to other resources, and install other software, such as DDoS zombies, if so desired.

DDoS (distributed denial of service) is a modified denial of service (DoS) attack. DoS attacks do not attempt to destroy or corrupt data, but attempt to use up a computing resource to the point at which normal work cannot proceed. The structure of a DDoS attack requires a master computer to control the attack, a target of the attack, and a number of computers in the middle that the master computer uses to generate the attack. These computers between the master and the target are variously called “agents” or “clients,” but are usually referred to as running “zombie” programs. The existence of a large number of agent computers in a DDoS attack acts to multiply the effect of the attack, and also helps to hide the identity of the originator of the attack.

Closely related to RATs and DDoS zombie clients are bot clients. Originally, bots were automated tools, frequently used on chat circuits for automatic administrative functions. However, various functions have been coded into pieces of malware for distribution to a large number of computers. One of the largest classes of bots are spambots, used to subvert a number of normal user computers into a spambotnet. As the name implies, these machines are used to generate and distribute spam. However, since the spambotnet is composed of a large number of disparate computers, it is much harder to isolate or shut down than a normal mail relay server. Many of these spambotnets are used to distribute advance-fee fraud messages, identity-theft solicitations (usually known as phishing), and new versions of malware and viruses.

There is a lot of controversy over a number of technologies generally described as adware or spyware. Most people would agree that the marketing functions are not specifically malicious, but what one person sees as “aggressive selling” another will see as an intrusion or invasion of privacy.

Shareware or freeware programs may have advertising for a commercial version or a related product, and users may be asked to provide some personal information for registration or to download the product. For example, an unregistered copy of the WinZip archiving program typically asks the user to register when the program is started, and the free version of the QuickTime

video player asks the user to buy the commercial version every time the software is invoked. Adware, however, is generally a separate program installed at the same time as a given utility or package, and continues to advertise products even when the desired program is not running. Spyware is, again, a system distinct from the software the user installed, and passes more information than simply a username and address back to the vendor: often these packages will report on Web sites visited or other software installed on the computer, and possibly compile detailed inventories of the interests and activities of a user.

The discussion of spyware often makes reference to cookies or Web bugs. Cookies are small pieces of information in regard to persistent transactions between the user and a Web site, but the information can be greater than the user realizes—for example, in the case of a company that provides content, such as banner ads, to a large number of sites. Cookies, limited to text data, are not malware, and can have no executable malicious content. Web bugs are links on Web pages or embedded in e-mail messages that contain links to different Web sites. A Web bug, therefore, passes a call, and information, unknown to the user, to a remote site. Most commonly a Web bug is either invisible or unnoticeable (typically it is one pixel in size) in order not to alert the user to its presence.

There is a persistent chain letter hoax that tells people to forward the message because it is part of a test of an e-mail tracking system. Although to date all such chain letter reports are false, such a system has been implemented and does use Web bug technology. The system is not reliable: Web bugs in e-mail rely on an e-mail system calling a Web browser function, and, while this typically happens automatically with systems like Microsoft Outlook and Internet Explorer, a mailer like Pegasus requires the function call to be established by the user, and warns the user when it is being invoked.

On susceptible systems, however, a good deal of information can be obtained: the mail system noted can frequently obtain the IP address of the user, the type and version of browser being used, the operating system of the computer, and the time the message was read.

Pranks are very much a part of the computer culture. So much so that you can now buy commercially produced joke packages that allow you to perform “Stupid Mac (or PC, or Windows) Tricks.” There are countless pranks available as shareware. Some make the computer appear to insult the user; some use sound effects or voices; some use special visual effects. A fairly common thread running through most pranks is that the computer is, in some way, nonfunctional. Many pretend to have detected some kind of fault in the computer (and some pretend to rectify such faults, of course making things worse). One entry in the virus field is PARASCAN, the paranoid scanner. It pretends to find large numbers of infected files, although it does not actually check for any infections.

Generally speaking, pranks that create some kind of announcement are not malware: viruses that generate a screen or audio display are actually quite rare. The distinction between jokes and Trojans is harder to make, but pranks are intended for amusement. Joke programs may, of course, result in a denial of service if people find the prank message frightening.

One specific type of joke is the “easter egg,” a function hidden in a program, and generally accessible only by some arcane sequence of commands. These may be seen as harmless, but note that they do consume resources, even if only disk space, and also make the task of ensuring program integrity very much more difficult.

FIRST-GENERATION VIRUSES

Many of the books and articles that are currently available to explain viruses were written based on the research that was done on the first generation of viruses. While these programs are still of interest to those who study the internal structures of operating systems, they operated much differently from the current crop of malicious software. First-generation viruses tended to spread very slowly, but to hang around in the environment for a long time. Later viruses tended to spread very rapidly, but also to die out relatively quickly.

Boot-Sector Viruses

Viruses are generally partly classified by the objects to which they attach. Worms may be seen as a type of virus that attaches to nothing. Most desktop computer operating systems have some form of boot sector, a specific location on the hard disk that contains programming to bootstrap the startup of a computer. Boot-sector infectors (BSIs) replace or redirect this programming in order to have the virus invoked, usually as the first programming running on the computer. Because the minimal built-in programming of the computer simply starts to read and execute material from a specific location on the disk, any code that occupies this location is run. BSIs copy themselves onto this location whenever they encounter any new disk.

BSIs would not appear to fit the definition of a virus infecting another program, since BSIs can be spread by disks that do not contain any program files. However, the boot sector of a normal MS-DOS disk, whether or not it is a “system” or bootable disk, always contains a program (even if it only states that the disk is not bootable), and so it can be said that a BSI is a “true” virus.

The terminology of BSIs comes from MS-DOS systems, and this leads to some additional confusion. The physical “first sector” on a hard drive is not the operating-system boot sector. On a hard drive the boot sector is the first “logical” sector. The number one position on a hard drive is the master boot record (MBR). Some viral programs, such as the Stoned virus, always attack the physical first sector: the boot sector on floppy disks and the master boot record on hard disks.

Thus, viral programs that always attack the boot sector might be termed “pure” BSIs, whereas programs like Stoned might be referred to as an “MBR type” of BSI. The term *boot-sector infector* is used for all of them, though, since all of them infect the boot sector on floppy disks.

File-Infecting Viruses

A file infector infects program (object) files. System infectors that infect operating system program files (such as COMMAND.COM in DOS) are also file infectors. File infectors can attach to the front of the object file

(prependers), attach to the back of the file and create a jump at the front of the file to the virus code (appenders), or overwrite the file or portions of it (overwriters). A classic is Jerusalem. A bug in early versions caused it to add itself over and over again to files, making the increase in file length detectable. (This has given rise to the persistent myth that it is a characteristic of a virus that it will fill up all disk space eventually; however, by far, the majority of file infectors add only minimally to file lengths.)

Polymorphic Viruses

Polymorphism (literally “many forms”) refers to a number of techniques that attempt to change the code string on each generation of a virus. These vary from using modules that can be rearranged to encrypting the virus code itself, leaving only a stub of code that can decrypt the body of the virus program when invoked. Polymorphism is sometimes also known as “self-encryption” or “self-garbling,” but these terms are imprecise and not recommended. Examples of viruses using polymorphism are Whale and Tremor. Many polymorphic viruses use standard “mutation engines” such as MtE. These pieces of code actually aid detection because they have a known signature.

Some authors have demonstrated that, in theory, polymorphic viruses cannot be perfectly detected. However, it is also theoretically true that no virus can be perfectly detected. In practical terms, polymorphic viruses present no particular problem, aside from the additional processing burden that algorithmic signature detection places on the scan.

A number of viruses also demonstrate some form of active detection avoidance, which may range from disabling of on-access scanners in memory to deletion of antivirus and other security software (Zonealarm is a favorite target) from the disk.

Virus-Creation Kits

The term *kit* usually refers to a program used to produce a virus from a menu or a list of characteristics. Use of a virus kit involves no skill on the part of the user. Fortunately, most virus kits produce easily identifiable code. Packages of antiviral utilities are sometimes referred to as tool kits, occasionally leading to confusion of the terms.

MACRO VIRUSES

A macro virus uses macro programming of an application such as a word processor. (Most known macro viruses use Visual BASIC for Applications [VBA] in Microsoft Word: some are able to cross between applications and function in, for example, a PowerPoint presentation and a Word document, but this ability is rare.) Macro viruses infect data files, and tend to remain resident in the application itself by infecting a configuration template such as MS Word’s NORMAL.DOT.

Although macro viruses infect data files, they are not generally considered to be file infectors: a distinction is generally made between program and data files. Macro viruses can operate across hardware or operating system platforms as long as the required application platform is present. (For example, many MS Word macro viruses can

operate on both the Windows and Macintosh versions of MS Word.) Examples are Concept and CAP. Melissa is also a macro virus, in addition to being an e-mail virus: it mailed itself around as an infected document.

Viruses contained in test or data files had been both theorized and tested prior to the macro viruses that used VBA. DOS batch files had been created that would copy themselves onto other batch files, and self-reproducing code had been created with the macro capabilities of the Lotus 1-2-3 spreadsheet program, but these were primarily academic exercises.

Macro viruses are not currently a major class of malware, and are certainly nothing in comparison to e-mail viruses and network worms. However, increasing numbers of applications have macro programming capabilities, and it is possible that macro viruses may become a problem again as the computing environment changes.

What Is a Macro?

As noted above, a macro is a small piece of programming contained in a larger data file. This differentiates it from a script virus that is usually a stand-alone file that can be executed by an interpreter, such as Microsoft Windows Script Host (.vbs files). A script virus file can be seen as a data file in that it is generally a simple text file, but it usually does not contain other data, and generally has some indicator (such as the .vbs extension) that it is executable. LoveLetter is a script virus.

Free Technology to Avoid Macro Viruses

A recommended defense is MacroList, written by A. Padgett Peterson. This is a macro itself, available for both Wintel and Macintosh machines. It will list all the macros in a document. Since most documents should not contain macros, any document that does should either have a really good reason for it, or be looked at with suspicion.

E-MAIL VIRUSES (THIRD GENERATION)

With the addition of programmable functions to a standard e-mail user agent (usually Microsoft Outlook), it became possible for viruses to spread worldwide in mere hours, as opposed to months.

The “Start” of E-Mail Viruses: Melissa

Melissa was far from the first e-mail virus. The first e-mail virus to successfully spread in the wild was CHRISTMA exec, in the fall of 1987. However, Melissa was certainly the first of the “fast burner” e-mail viruses, and the first to come to wide public attention.

The virus, generally referred to as W97M.Melissa is a Microsoft Word macro virus. The name *Melissa* comes from the class module that contains the virus. The name is also used in the registry flag set by the virus. The virus is spread, of course, by infected Word documents. What has made it the “bug du jour” is that it spreads itself via e-mail.

Melissa was originally posted to the alt.sex newsgroup. At that time it was LIST.DOC, and purported to be a list of passwords for sex sites. If you get a message with a Melissa

infected document, and do whatever you need to do to “invoke” the attachment, and have Word on your system as the default program for .doc files, Word starts up, reads in the document, and the macro is ready to start. Assuming that the macro starts executing, several things happen. The virus first checks to see if Word 97 (Word 8) or Word 2000 (Word 9) is running. If so, it reduces the level of the security warnings on Word so that you will receive no future warnings. In Word97, the virus disables the Tools/Macro menu commands, the Confirm Conversions option, the MS Word macro virus protection, and the Save Normal Template prompt. It “upconverts” to Word 2000 quite nicely, and there disables the Tools/Macro/Security menu.

Specifically, under Word 97 it blocks access to the Tools/Macro menu item, meaning you cannot check any macros. It also turns off the warnings for conversion, macro detection, and to save modifications to the NORMAL.DOT file. Under Word 2000 it blocks access to the menu item that allows you to raise your security level, and sets your macro virus detection to the lowest level—that is, none. Since the access to the macro security menu item is blocked, you must delete the infected NORMAL.DOT file in order to regain control of your security settings. Note that this will also lose all of your global templates and macros. Word users who make extensive use of macros are advised to keep a separate backup copy of a clean NORMAL.DOT in some safe location to avoid problems with macro virus infections.

After this, the virus checks for the HKEY_CURRENT_USER\Software\Microsoft\Office\Melissa? registry key with a value of “... by Kwyjibo”. (The “kwyjibo” entry seems to be a reference to the “Bart the Genius” episode of the “Simpsons” television program where this word was used to win a Scrabble match.) If this is the first time you have been infected, then the macro starts up Outlook 98 or higher, in the background, and sends itself as an attachment to the “top” fifty names in each of your address lists. (Melissa will not use Outlook Express. Also, Outlook 97 will not work.) Most people have only one (the default is “Contacts”), but if you have more than one, then Outlook will send more than fifty copies of the message. Outlook also sorts address lists such that mailing lists are at the top of the list, so this can get a much wider dispersal than just fifty copies of the message/virus.

Once the messages have been sent, the virus sets the Melissa flag in the registry, and looks for it to check whether to send itself out on subsequent infections. If the flag does not persist, then there will be subsequent mass mailings. Because the key is set in HKEY_CURRENT_USER, system administrators may have set permissions such that changes made are not saved, and thus the key will not persist. In addition, multiple users on the same machine will likely each trigger a separate mailout, and the probability of cross infection on a common machine is very high.

Since it is a macro virus, Melissa will infect your NORMAL.DOT, and will infect all documents thereafter. The macro within NORMAL.DOT is “Document_Close()” so that any document that is worked on (or created) will be infected when it is closed. When a document is infected the macro inserted is “Document_Open()” so that the macro runs when the document is opened.

Note that not using Outlook does not protect you from the virus, it only means that the fifty copies will not be

automatically sent out. If you use Word but not Outlook, you will still be infected, and may still send out infected documents on your own. Originally the virus would not invoke the mailout on Macintosh systems. However, infected documents would be stored, and, recently, when Outlook became available for Macs, there was a second wave of Melissa mailings.

The message appears to come from the person just infected, of course, since it really is sent from that machine. This means that when you get an "infected" message it will probably appear to come from someone you know and deal with. The subject line is "Important Message From: [name of sender]" with the name taken from the registration settings in Word. The text of the body states "Here is that document you asked for ... don't show anyone else ;-)". Thus, the message is easily identifiable: that subject line, the very brief message, and an attached Word document (file with a .doc extension to the filename).

However, note that, as with any Microsoft Word macro virus, the source code travels with the infection, and it was very easy for people to create variations of Melissa. Within days of Melissa there was a similar Excel macro virus, called "Papa."

One rather important point: the document passed is the active document, not necessarily the original posted on alt.sex. So, for example, if I am infected, and prepare some confidential information for you in Word, and send you an attachment with the Word document, containing sensitive information that neither you nor I want made public and you read it in Word, and you have Outlook on your machine, then that document will be mailed out to the top fifty people in your address book, and so forth.

How to Avoid E-Mail Viruses

It really is very simple to avoid e-mail viruses: don't double click on any attachments that come with your e-mail. We used to say not to run any programs that came from someone you do not know, but many e-mail viruses spread using the identity of the owner of the infected computer, so that is no longer any protection. Do not run anything you receive, unless you know, from some separate verification, that this person intended to send you something, and that it is something you need, and that the person sending it is capable of protecting themselves from infection.

It is also somewhat safer to use a mail program other than Outlook, since some versions of Outlook allowed attachments to run even before the user reads the message to which they are attached.

Worms (First and Third Generation)

In autumn 1988, the Internet/UNIX/Morris Worm did not actually bring the Internet in general and email in particular to the proverbial grinding halt. It was able to run and propagate only on machines running specific versions of the UNIX operating system on specific hardware platforms. However, given that the machines that are connected to the Internet also comprise the transport mechanism for the Internet, a "minority group" of server-class machines, thus affected, degraded the performance of the Net as a whole. Indeed, it can be argued that

despite the greater volumes of mail generated by Melissa and LoveLetter and the tendency of some types of mail servers to achieve meltdown when faced with the consequent traffic, the Internet as a whole has proved to be somewhat more resilient in recent years.

During the 1988 mailstorm, a sufficient number of machines had been affected to impair e-mail and distribution-list mailings. Some mail was lost, either by mailers that could not handle the large volumes that "backed up," or by mail queues being dumped in an effort to disinfect systems. Most mail was substantially delayed. In some cases, mail would have been rerouted via a possibly less efficient path after a certain time. In other cases, backbone machines, affected by the problem, were simply much slower at processing mail. In still others, mail-routing software would crash or be taken out of service, with a consequent delay in mail delivery. Ironically, electronic mail was the primary means that the various parties attempting to deal with the trouble were trying to use to contact each other.

In many ways, the Internet Worm is the story of data security in miniature. The Worm used "trusted" links, password cracking, security "holes" in standard programs, standard and default operations, and, of course, the power of virus replication.

"Big Iron" mainframes and other multi-user server systems are generally designed to run constantly, and execute various types of programs and procedures in the absence of operator intervention. Many hundreds of functions and processes may be running all the time, expressly designed neither to require nor to report to an operator. Some such processes cooperate with each other; others run independently.

In the UNIX world, such small utility programs are referred to as "daemons," after the supposedly subordinate entities that take over mundane tasks and extend the power of the "wizard," or skilled operator. Many of these utility programs deal with the communications between systems. "Mail," in the network sense, covers much more than the delivery of text messages between users. Network mail between systems may deal with file transfers, the routing of information for reaching remote systems, or even upgrades and patches to system software.

When the Internet Worm was well established on a machine, it would try to infect another. On many systems, this attempt was all too easy, since computers on the Internet are meant to generate activity on each other, and some had no protection in terms of the type of access and activity allowed.

The finger program is one that allows a user to obtain information about another user. The server program, fingerd, is the daemon that listens for calls from the finger client. The version of fingerd common at the time of the Internet Worm had a minor problem: it did not check how much information it was given. It would take as much as it could hold and leave the rest to overflow. "The rest," unfortunately, could be used to start a process on the computer, and this process was used as part of the attack. This kind of buffer overflow attack continues to be very common, taking advantage of similar weaknesses in a wide range of applications and utilities.

The sendmail program is the engine of most mail-oriented processes on UNIX systems connected to the Internet. In principle, it should only allow data received

from another system to be passed to a user address. However, there is a debug mode, which allows commands to be passed to the system. Some versions of UNIX were shipped with the debug mode enabled by default. Even worse, the debug mode was often enabled during installation of send-mail for testing and then never turned off.

When the Worm accessed a system, it was fed with the main program from the previously infected site. Two programs were used, one for each infected platform. If neither program could work, the Worm would erase itself. If the new host was suitable, the Worm looked for further hosts and connections. The program also tried to break into user accounts on the infected machine. It used standard password-cracking techniques such as simple variations on the name of the account and the user. It carried a dictionary of words likely to be used as passwords, and would also look for a dictionary on the new machine and attempt to use that as well. If an account was “cracked,” the Worm would look for accounts that this user had on other computers, using standard UNIX tools.

Following the Internet Worm, and a few similar examples in late 1988 and early 1989, worm examples were very infrequent during the 1990s. By spring 2001, a number of examples of Linux malware had been seen. Interestingly, while the Windows viruses generally followed the CHRISTMA exec style of having users run the scripts and programs, the new Linux worms were similar to the Internet/Morris/UNIX worm in that they rely primarily on bugs in automatic networking software.

The Ramen worm makes use of security vulnerabilities in default installations of Red Hat Linux 6.2 and 7.0 using specific versions of the wu-ftp, rpc.statd, and LPRng programs. The worm defaces Web servers by replacing index.html, and scans for other vulnerable systems. It does this initially by opening an ftp connection and checking the remote system's ftp banner message. If the system is vulnerable, the worm uses one of the exploitable services to create a working directory, and then downloads a copy of itself from the local (attacking) system.

Lion uses a buffer overflow vulnerability in the bind program to spread. When it infects, Lion sends a copy of output from the ifconfig command, /etc/passwd, and /etc/shadow to an e-mail address in the china.com domain. Next the worm adds an entry to etc/inetd.conf and restarts inetd. This entry would allow Lion to download components from a (now closed) Web server located in China. Subsequently, Lion scans random class B subnets in much the same way as Ramen, looking for vulnerable hosts. The worm may install a rootkit onto infected systems. This backdoor disables the syslogd daemon and adds a trojanized ssh (secure shell) daemon.

Code Red uses a known vulnerability to target Microsoft IIS (Internet information server) Web servers. Despite the fact that a patch for the loophole had been available for five months prior to the release of Code Red, the worm managed to infect 350,000 servers within nine to thirteen hours. When a host is infected it starts to scan for other hosts to infect. It probes random IP addresses but the code is flawed by always using the same seed for the random number generator. Therefore, each infected server starts probing the same addresses that have been done before. (It was this bug that allowed the establishment of such a precise count for the number of infections.) During a

certain period of time the worm only spreads, but then it initiates a DoS attack against www1.whitehouse.gov. However, since this particular machine name was only an overflow server, it was taken offline prior to the attack and no disruptions resulted. The worm changed the front page of an infected server to display certain text and a background color of red, hence the name of the worm.

Code Red definitely became a media virus. Although it infected at least 350,000 machines within hours, it had probably almost exhausted its target population by that time. In spite of this, the FBI held a press conference to warn of the worm. Code Red seems to have spawned quite a family, each variant improving slightly on the random probing mechanism. In fact, there is considerable evidence that Nimda is a descendent of Code Red.

Nimda variants all use a number of means to spread. Like Code Red, Nimda searches random IP addresses for unpatched Microsoft IIS machines. Nimda will also alter Web pages in order to download and install itself on computers browsing an infected Web site using a known exploit in Microsoft Internet Explorer's handling of Java. Nimda will also mail itself as a file attachment and will install itself on any computer on which the file attachment is executed. Nimda is normally e-mailed in HTML format, and may install automatically when viewed using a known exploit in Microsoft Internet Explorer. Nimda will also create e-mail and news files on network shares and will install itself if these files are opened.

Although Nimda would attack both servers and desktop machines, it did so through the use of a variety of vectors, and is known as a multipartite virus. The most successful “pure” worm was probably Blaster. It made a direct connection to any machine on the Internet, including desktops, since it used a vulnerability in Microsoft's DCOM function, which was enabled by default on all versions of Windows. At the height of the Blaster attacks, an unprotected machine exposed to the Internet would be infected within two minutes.

DETECTION TECHNIQUES

All antiviral technologies are based on the three classes outlined by Fred Cohen in his early research. The first type performs an ongoing assessment of the functions taking place in the computer, looking for operations known to be dangerous. The second checks regularly for changes in the computer system, where changes should occur only infrequently. The third examines files for known code found in previous viruses.

Within these three basic types of antivirus software, implementation details vary greatly. Some systems are meant only for use on stand-alone systems, while others provide support for centralized operation on a network. With Internet connections being so important now, many packages can be run in conjunction with content scanning gateways or firewalls.

String Search (Signature-Based)

Scanners examine files, boot sectors and/or memory for evidence of viral infection. They generally look for viral signatures, sections of program code that are known to be in specific virus programs but not in most other

programs. Because of this, scanning software will generally detect only known viruses and must be updated regularly. Some scanning software has resident versions that check each file as it is run.

In years past, search strings were generally found during a general analysis of the code of the virus. Currently, most antivirus companies have automated systems that run suspected programs on “goat” machines, in order to assess changes made. Goat machines are sometimes created by running virtual machines inside other platforms, such as running an emulator of a Microsoft Windows computer on a Linux computer platform. In this case, even if a Windows-based virus escapes from the controls in the virtual machine, it will find itself in an unfamiliar platform, and is therefore unable to proceed further.

Scanners have generally been the most popular form of antiviral software, probably because they make a specific identification. In fact, scanners offer somewhat weak protection, since they require regular updating. Scanner identification of a virus may not always be dependable: a number of scanner products have been known to identify viruses based on common families rather than definitive signatures.

Change Detection (Integrity Checking)

Change detection software examines system and/or program files and configuration, stores the information, and compares it against the actual configuration at a later time. Most of these programs perform a checksum or cyclic redundancy check (CRC) that will detect changes to a file even if the length is unchanged. Some programs will even use sophisticated encryption techniques to generate a signature that is, if not absolutely immune to malicious attack, prohibitively expensive, in processing terms, from the point of view of a piece of malware.

Change-detection software should also note the addition of completely new entities to a system. It has been noted that some programs have not done this, and allowed the addition of virus infections or malware. Change-detection software is also often referred to as integrity-checking software, but this term may be somewhat misleading. The integrity of a system may have been compromised before the establishment of the initial baseline of comparison.

A sufficiently advanced change-detection system, which takes all factors including system areas of the disk and the computer memory into account, has the best chance of detecting all current and future viral strains. However, change detection also has the highest probability of false alarms, since it will not know whether a change is viral or valid. The addition of intelligent analysis of the changes detected may assist with this failing.

Most antivirus companies and vendors now use change-detection systems for automated assessment of viruses. The virus is allowed to run in a restricted environment such as a virtual machine, and modifications to the system are noted. Generally this information is used to create signatures for scanning programs.

Real-Time Scanning

Real-time, or on-access, scanning is not really a separate type of antivirus technology. It uses standard signature

scanning, but attempts to deal with each file or object as it is accessed, or comes into the machine. Because on-access scanning can affect the performance of the machine, vendors generally try to take shortcuts in order to reduce the delay when a file is read. Therefore, real-time scanning is significantly less effective at identifying virus infections than a normal signature scan of all files.

Real-time scanning is one way to protect against viruses on an ongoing basis, but it should be backed up with regular full scans.

Heuristic Scanning

A recent addition to scanners is intelligent analysis of unknown code, currently referred to as “heuristic scanning.” It should be noted that heuristic scanning does not represent a new type of antivirus software. More closely akin to activity monitoring functions than traditional signature scanning, this looks for “suspicious” sections of code that are generally found in virus programs. Although it is possible for normal programs to want to “go resident,” look for other program files, or even modify their own code, such activities are telltale signs that can help an informed user come to some decision about the advisability of running or installing a given new and unknown program. Heuristics, however, may generate a lot of false alarms, and may either scare novice users, or give them a false sense of security after “wolf” has been cried too often.

Permanent Protection

The ultimate object, for computer users, is to find some kind of antiviral system that you can set and forget: that will take care of the problem without further work or attention on your part. Unfortunately, as previously noted, it has been proved that such protection is impossible. On a more practical level, every new advance in computer technology brings more opportunity for viruses and malicious software. As it has been said in political and social terms, so too the price of safe computing is constant vigilance.

Vaccination

In the early days of antiviral technologies, some programs attempted to add change detection to every program on the disk. Unfortunately, these packages, frequently called “vaccines,” sometimes ran afoul of different functions within normal program which were designed to detect accidental corruption on a disk. No program has been found that can fully protect a computer system in more recent operating environments.

Some vendors have experimented with an “autoimmune” system, whereby an unknown program can be sent for assessment, and, if found to be malicious, a new set of signatures created and distributed automatically. This type of activity does show promise, but there are significant problems to be overcome.

Activity Monitoring (Behavior-Based)

An activity monitor performs a task very similar to an automated form of traditional auditing: it watches for

suspicious activity. It may, for example, check for any calls to format a disk or attempts to alter or delete a program file while a program other than the operating system is in control. It may be more sophisticated, and check for any program that performs “direct” activities with hardware, without using the standard system calls.

Activity monitors represent some of the oldest examples of antivirus software, and are usually effective against more than just viruses. Generally speaking, such programs followed in the footsteps of the earlier anti-Trojan software, such as BOMBSQAD and WORMCHEK in the MS-DOS arena, which used the same “check what the program tries to do” approach. This tactic can be startlingly effective, particularly given the fact that so much malware is slavishly derivative and tends to use the same functions over and over again.

It is, however, very hard to tell the difference between a word processor updating a file and a virus infecting a file. Activity-monitoring programs may be more trouble than they are worth because they can continually ask for confirmation of valid activities. The annals of computer virus research are littered with suggestions for virusproof computers and systems that basically all boil down to the same thing: if the operations that a computer can perform are restricted, virus programs can be eliminated. Unfortunately, so is most of the usefulness of the computer.

PREVENTION AND PROTECTION TECHNIQUES

In regard to protection against viruses, it is germane to mention the legal situation with regard to viruses. Note that a virus may be created in one place and still spread worldwide, so issues of legal jurisdiction may be confused. In addition, specific activity may have a bearing: in the United States it may be legal to write a virus, but illegal to release it. However, in the first sixteen years of the existence of viruses as a serious occurrence in the computing environment, only five people have been convicted of writing computer viruses, and in all five cases the defendants entered guilty pleas. Therefore, it is as well not to rely on criminal prosecutions as a defense against viruses.

The converse, however, is not true. If you are infected with a virus, and it can be demonstrated that your system subsequently sent a message that infected someone else, you may be legally liable. Thus, it is important to protect yourself from infection, even if the infection will not inconvenience you or cause loss to your business.

Training and some basic policies can greatly reduce the danger of infection. A few guidelines that can really help in the current environment are:

- Don't double-click on attachments.
- When sending attachments, be really specific when describing them.
- Do not blindly use Microsoft products as a company standard.
- Disable Windows Script Host.
- Disable ActiveX.
- Disable VBScript.

- Disable JavaScript.
- Don't send HTML-formatted e-mail.
- Use more than one scanner, and scan everything.

There are now companies that will provide insurance against virus attacks. This insurance is generally an extensive of “business loss of use” insurance, and potential buyers would do well to examine the policies very closely to see the requirements for making a claim against it, and also conditions that may invalidate payment.

Unfortunately, the price of safe computing is constant vigilance. Until 1995 it was thought that data files could not be used to transport a virus. Until 1998 it was thought that e-mail could not be used to automatically infect a machine. Advances in technology are providing new viruses with new means of reproduction and spread. Two online virus encyclopedias (F-Secure/Data Fellows Virus Encyclopedia; Sophos Virus Encyclopedia) are in the reference list, and information about new viruses can be reliably determined at these sites.

NON-PC-PLATFORM VIRUSES

As noted, many see viruses only in terms of DOS or Windows-based programs on the Intel platform. Although there are many more PC viruses than on other platforms (primarily because there are more PCs in use than other computers), other platforms have many examples of viruses. Indeed, I pointed out earlier that the first successful viruses were probably created on the Apple II computer.

CHRISTMA exec, the Christmas Tree Virus/Worm, sometimes referred to as the “BITNET chain letter,” was probably the first major malware attack across networks. It was launched on December 9, 1987 and spread widely on BITNET, EARN, and IBM's internal network (VNet). It has a number of claims to a small place in history. It was written, unusually, in REXX, a scripting system used to aid with automating of simple user processes. It was mainframe-hosted (on VM/CMS systems) rather than microcomputer-hosted, quaint though that distinction sounds nowadays when the humblest PC can run UNIX.

CHRISTMA presented itself as a chain letter inviting the recipient to execute its code. This involvement of the user leads to the definition of the first e-mail virus, rather than a worm. When it was executed, the program drew a Christmas tree and mailed a copy of itself to everyone in the account holder's equivalent to an address book, the user files NAMES and NETLOG. Conceptually, there is a direct line of succession from this worm to the social engineering worm/Trojan hybrids of today.

In the beginning of the existence of computer viruses actually proliferating in the wild, the Macintosh computer seemed to have as many interesting viruses as those in the DOS world. The Brandau, or “Peace” virus, became the first to infect commercially distributed software, while the nVIR virus sometimes infected as many as 30 percent of the computers in a given area. However, over time it has become evident that any computer can be made to spread a virus, and the fact that certain systems have more than others seems to be simply a factor of the number of computers, of a given type, in use.

CONCLUSION

Malware is a problem that is not going away. Unless systems are designed with security as an explicit business requirement, which current businesses are not supporting through their purchasing decisions, malware will be an increasingly significant problem for networked systems.

It is the nature of networks that what is a problem for a neighboring machine may well become a problem for local systems. In order to prevent this, it is critical that the information security professional help business leaders recognize the risks incurred by their decisions, and help to mitigate those risks as effectively and economically as possible. With computer viruses and similar phenomena, each system that is inadequately protected increases the risk to all systems to which it is connected. Each system that is compromised can become a system that infects others. If you are not part of the solution, in the world of malware, you are most definitely part of the problem.

GLOSSARY

Terms derived from the "Glossary of Communications, Computer, Data, and Information Security Terms," posted online at <http://victoria.tc.ca/techrev/secgloss.htm>.

Activity Monitor A type of antiviral software that checks for signs of suspicious activity, such as attempts to rewrite program files, format disks, and so forth. Some versions of activity monitors will generate an alert for such operations, while others will block the behavior.

Change Detection Antiviral software that looks for changes in the computer system. A virus must change something, and it is assumed that program files, disk system areas and certain areas of memory should not change. This software is very often referred to as "integrity-checking" software, but it does not necessarily protect the integrity of data, nor does it always assess the reasons for a possibly valid change. Change detection using strong encryption is sometimes also known as "authentication software."

False Negative There are two types of "false" reports from antiviral software. A false negative report is when an antivirus program reports no viral activity or presence when a virus is present. References to false negatives are usually made only in technical reports. Most people simply refer to an antivirus program "missing" a virus. In general security terms, a false negative is called a "false acceptance," or "Type II error."

False Positive The second kind of false report that an antiviral can make is to report the activity or presence of a virus when there is, in fact, no virus. False positive has come to be very widely used among those who know about virus and antivirus programs. Very few use the analogous term, "false alarm." In general security terms, a false positive is known as a "false rejection," or a "Type I error."

Heuristic In general, *heuristic* refer to trial-and-error or seat-of-the-pants thinking rather than formal rules. In antivirus jargon, however, the term has developed a specific meaning regarding the examination of program code for functions or opcode strings known to

be associated with viral activity. In most cases this is similar to activity monitoring but without actually executing the program; in other cases, code is run under some type of emulation. In recent years, the meaning has expanded to include generic signature scanning meant to catch a group of viruses without making definite identifications.

Macro Virus A macro is a small piece of programming in a simple language, used to perform a simple, repetitive function. Microsoft's Word Basic and Visual BASIC for Applications (VBA) macro languages can include macros in data files, and have sufficient functionality to write complete viruses.

Malware A general term used to refer to all forms of malicious or damaging software, including virus programs, Trojans, logic bombs and the like.

Multipartite Formerly, a virus program that would infect both boot sectors and files; now refers to a virus that will infect multiple types of objects or that reproduces in multiple ways.

Payload Used to describe the code in a viral program that is not concerned with reproduction or detection avoidance. The payload is often a message but is sometimes coded to corrupt or erase data.

Polymorphism Techniques that use some system of changing the "form" of the virus on each infection to try to avoid detection by signature-scanning software. Less sophisticated systems are referred to as "self-encrypting."

Rootkit A script, set of scripts, or package of modified system programs used for gaining unauthorized root privileges (or equivalent supervisory powers) on a compromised system. Recently, media usage has expanded this definition to include any software that can hide software or processes on a system, but this usage is vague and should be avoided.

Scanner A program that reads the contents of a file looking for code known to exist in specific virus programs. Also known as a "signature scanner."

Stealth Various technologies used by virus programs to avoid detection on disk. The term properly refers to the technology, and not a particular virus.

Trojan Horse A program that either pretends to have or is described as having a (beneficial) set of features but that either instead of or in addition to that contains a damaging payload. Most frequently the usage is shortened to Trojan.

Virus A final definition has not yet been agreed on by all researchers. A common definition is, "a program that modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen, although Dr. Cohen's actual definition is in mathematical form. Another possible definition is, "an entity that uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action."

Wild, in the A jargon reference to virus programs that have been released into, and successfully spread in, the normal computer user community and environment. It is used to distinguish viral programs that are written and tested in a controlled research environment, without escaping, from those that are uncontrolled "in the wild."

Worm A self-reproducing program that is distinguished from a virus by copying itself without being attached to a program file, or that spreads over computer networks, particularly via e-mail. A recent refinement is the definition of a worm as spreading without user action, for example by taking advantage of loopholes and trapdoors in software.

INTRODUCTION

Denial of service (DoS) attacks have become a major threat to current computer networks. Early DoS attacks were technical games played among underground attackers. For example, an attacker might want to get control of an Internet relay chat (IRC) channel by performing DoS attacks against the channel owner. Attackers could get recognition in the underground community via taking down popular Web sites. Because easy-to-use DoS tools, such as Trinoo (Dittrich 1999), can be easily downloaded from the Internet, normal computer users can become DoS attackers as well. They sometime coordinately expressed their views by launching DoS attacks against organizations whose policies they disagreed with. DoS attacks also appeared in illegal actions. Companies might use DoS attacks to knock off their competitors in the market. Extortion via DoS attacks were on rise in the past years (Pappalardo and Messmer 2005). Attackers threatened online businesses with DoS attacks and requested payments for protection.

Known DoS attacks in the Internet generally conquer the target by exhausting its resources, which can be anything related to network computing and service performance, such as link bandwidth, TCP connection buffers, application/service buffer, CPU cycles, etc. Individual attackers can also exploit vulnerability, break into target servers, and then bring down services. Because it is difficult for attackers to overload the target's resource from a single computer, many recent DoS attacks have been launched via a large number of distributed attacking hosts in the Internet. These attacks are called "distributed denial of service" (DDoS) attacks. In a DDoS attack, because the aggregation of the attacking traffic can be tremendous compared with the victim's resources, the attack can force the victim to significantly downgrade its service performance or even stop delivering any service. Compared with conventional DoS attacks that could be addressed by securing

service systems better prohibiting unauthorized remote or local access, DDoS attacks are more complex and harder to prevent. Since many unwitting hosts are involved in DDoS attacks, it is challenging to distinguish the attacking hosts and react against them. In recent years, DDoS attacks have increased in frequency, sophistication, and severity because computer vulnerabilities are increasing quickly (CERT 2006; Houle and Weaver 2001), which enable attackers to break into and install various attacking tools in many computers.

Wireless networks also suffer from DoS attacks because mobile nodes (such as laptops, cell phones, etc.) share the same physical media for transmitting and receiving signals; and mobile computing resources (such as bandwidth, CPU, and power) are usually more constrained than those available to wired nodes. In a wireless network, a single attacker can easily forge, modify, or inject packets to disrupt connections between legitimate mobile nodes and cause DoS effects.

In this chapter, we will provide an overview on existing DoS attacks and major defense technologies. The chapter is organized as follows. In the next section we present an overview of major DoS attack techniques on the Internet. We also discuss the reasons why a DoS attack can succeed and why defense is difficult. In the subsequent section, a taxonomy of DDoS attacks is discussed according to several major attack characteristics. Then we present an overview of recent DDoS defense technologies according to their deployment locations. Then we discuss DoS attacks and defenses in wireless networks according to different network layers. Finally, we present our conclusions.

OVERVIEW OF DOS ATTACKS ON THE INTERNET

In this section, we overview the common DDoS attack techniques and discuss why attacks succeed fundamentally.

Attack Techniques

Many attack techniques can be used for DoS purposes as long as they can disable service or downgrade service performance by exhausting resources for providing services. Although it is impossible to enumerate all existing attack techniques, we describe several representative network-based and host-based attacks in this section to illustrate attack principles. Readers can also find complementary information on DoS attacks in Handley and Rescorla (2006) and Mirkovic et al. (2005).

Network-Based Attacks

TCP SYN Flooding. DoS attacks often exploit stateful network protocols (Jian 2000; Shannon, Moore, and Claffy 2002), because these protocols consume resources to maintain states. TCP SYN flooding is one such attack and has had a wide impact on many systems. When a client attempts to establish a TCP connection to a server, the client first sends a SYN (synchronize) message to the server. The server then acknowledges by sending a SYN-ACK (synchronize-acknowledgment) message to the client. The client completes the establishment by responding with an ACK message. The connection between the client and the server is then opened, and the service-specific data can be exchanged. The abuse arises at the half-open state, when the server is waiting for the client's ACK message after sending the SYN-ACK message to the client (CERT 1996). The server needs to allocate memory for storing the information of the half-open connection. The memory will not be released until either the server receives the final ACK message or the half-open connection expires. Attacking hosts can easily create half-open connections via spoofing source IPs in SYN messages or ignoring SYN-ACKs. The consequence is that the final ACK message will never be sent to the victim. Because the victim normally allocates only a limited space in its process table, too many half-open connections will soon fill the space. Even though the half-open connections will eventually expire because of the time-out, zombies can aggressively send spoofed TCP SYN packets requesting connections at a much higher rate than the expiration rate. Finally, the victim will be unable to accept any new incoming connection and thus cannot provide services.

ICMP Smurf Flooding. ICMP (Internet control message protocol) is often used to determine whether a computer on the Internet is responding. To achieve this task, an ICMP echo request packet is sent to a computer. If the computer receives the request packet, it will return an ICMP echo reply packet. In a smurf attack, attacking hosts forge ICMP echo requests having the victim's address as the source address and the broadcast address of these remote networks as the destination address (CERT 1998). As depicted in Figure 1, if the firewall or router of the remote network does not filter the special crafted packets, they will be delivered (broadcast) to all computers on that network. These computers will then send ICMP echo reply packets back to the source (i.e., the victim) carried in the request packets. The victim's network is thus congested.

User Datagram (UDP) Flooding. By patching or redesigning the implementation of TCP and ICMP protocols,

Figure 1: ICMP smurf attack

current networks and systems have incorporated new security features to prevent TCP and ICMP attacks. Nevertheless, attackers may simply send a large number of UDP packets toward a victim. Since an intermediate network can deliver higher traffic volume than the victim's network can handle, the flooding traffic can exhaust the victim's connection resources. Pure flooding can be done with any type of packets. Attackers can also choose to flood service requests so that the victim cannot handle all requests with its constrained resources (i.e., service memory or CPU cycles). Note that UDP flooding is similar to flash crowds that occur when a large number of users try to access the same server simultaneously. However, the intent and the triggering mechanisms for DDoS attacks and flash crowds are different.

Intermittent Flooding. Attackers can further tune their flooding actions to reduce the average flooding rate to a very low level while achieving equivalent attack impacts on legitimate TCP connections. In shrew attacks (Kuzmanovic and Knightly 2003), attacking hosts can flood packets in a burst to congest and disrupt existing TCP connections. Since all disrupted TCP connections will wait a specific period (called "retransmission time out" [RTO]) to retransmit lost packets, attacking hosts can flood packets at the next RTO to disrupt retransmission. Thereby, attacking hosts can synchronize their flooding at the following RTOs and disable legitimate TCP connections, as depicted in Figure 2. Such collaboration among attacking hosts not only reduces overall flooding traffic, but also helps avoid detection. Similar attack techniques targeting services with congestion control mechanisms for quality of service (QoS) have been discovered by Guirguis et al. (2005). When a QoS-enabled server receives a burst of service requests, it will temporarily throttle incoming requests for a period until previous requests have been processed. Thus, attackers can flood requests at a

Figure 2: Low-rate intermittent flooding

Figure 3: An example of attack against application deficiency

pace to keep the server throttling the incoming requests and achieve the DoS effect. Guirguis's study showed that a burst of 800 requests can bring down a Web server for 200 seconds, and thereby the average flooding rate could be as low as four requests per second.

Host-Based Attacks

In addition to misusing network protocols, attackers can also launch DoS attacks via exploiting vulnerabilities in target's applications and systems. Different from network-based attacks, this type of attack is application-specific—that is, it exploits particular algorithms (Crosby and Wallach 2003), memory structure (Cowan et al. 2003), authentication protocols (Dean and Stubblefield 2001, Zhang and Chen 2005), implementation (CERT 1997), etc. Attacks can be launched either from a single host as a conventional intrusion or from a number of hosts as a network based-DDoS attack. The traffic of host-based attacks may not be as high as that of network-based attacks, because application flaws and deficiencies can easily crash applications or consume a tremendous amount of computer resources. Several example attacks are described as follows.

Dean and Stubblefield (2001) identified that attackers could easily arrange an attack such that e-commerce Web sites remain available, but clients are unable to complete any purchase. Such an attack is based on going after the secure server that processes credit card payments. In such e-commerce applications, the secure sockets layer/transport layer security (SSL/TLS) protocol is used to make secure connections between clients and servers. The protocol allows a client to request the server to perform an RSA decryption. RSA decryption is an expensive operation. For instance, a large secure Web site can process a few thousand RSA decryptions per second. If a secure sockets layer (SSL) handshake request takes 200 bytes and a server can process 5000 decryptions per second, 1 MBps of requests is sufficient to paralyze an e-commerce site, which is a hard-to-notice small amount of traffic.

Attackers can also send large modulo values via client certificates to increase the RSA computation per authentication. Consequently, mutual authentication cannot be done quickly and service performance is downgraded.

Researchers also found that attackers could exploit algorithmic deficiencies in many applications' data structures to launch low-bandwidth DoS attacks (Crosby and Wallach 2003). Because many frequently used data structures have an "average-case" expected running time that is far more efficient than the worst case, attackers can carefully choose inputs to produce the worst scenario in data structures. Crosby and Wallach demonstrated this kind of DoS attack against the hash-table implementations. Normally, inserting n inputs into a hash table requires $O(n)$ computation on average (Figure 3a). However, inputs could collide if they have the same hash value. Then, some applications use open addressing to solve the collision following a deterministic strategy to probe for empty hash-table entries. In the worst case, in which all n inputs collide, $O(n^2)$ computation will be required (Figure 3b). Crosby and Wallach found that attackers can easily figure out such collision inputs in some hash algorithms, and demonstrated that attackers could bring down two versions of Perl, the Squid Web proxy, and the Bro intrusion-detection system via inputting strings that collide to crash the critical hash tables in these applications.

Attack Network

Many recent DoS attacks (also called "DDoS attacks") were launched from distributed attacking hosts. A DDoS attack is launched in two phases. First, an attacker builds an attack network that is distributed and consists of thousands of compromised computers (called zombies, bots, or attacking hosts). Then, the attacking hosts flood a tremendous volume of traffic towards victims either under the command of the attacker or automatically.

To build an attack network, the attacker looks for computers that are poorly secured, such as those not having

Figure 4: Attack network (botnet)

been properly patched. In general, a vulnerable host can be compromised via two types of approaches. One is to entice users to run malicious programs, such as a virus, a spyware, or a Trojan horse carried in malicious e-mails, files, or Web pages. The other approach is via automated malicious programs, such as worms that can automatically scan vulnerable remote computers. The vulnerability in these computers is then exploited to allow the attacker to break into and install DoS attacking programs that further scan other hosts, install backdoors, and flood packets. The attacker is thus called the master of these compromised computers (zombies). Some DoS programs have the ability to register the compromised computer as a member in the attack network controlled by the attacker. In addition, the newly compromised computers will automatically repeat the scanning and exploiting process to look for other vulnerable computers. Because of the self-propagation, a large attack network can quickly be built to include hundreds or thousands of computers.

A botnet (HoneyNet 2005) is an example of attack networks (depicted in Figure 4) in which an attacker controls a large number of zombies. In the attack network, zombies are called "bots." They can be used to scan and subvert other vulnerable computers to new bots. They can communicate with the attacker and synchronize their actions via covert channels. For instance, Internet relay chat (IRC) is a legitimate communication service, and the attacker sends commands via an IRC channel to control the zombies. Nevertheless, the attacker usually disguises his control packets as legitimate chat traffic. The discovery of a zombie may not reveal the identification of other zombies or the attacker. To further avoid discovery, the attacker can frequently switch IRC channels. In addition, because IRC service is maintained in a distributed manner, an IRC server can host a particular IRC channel anywhere in the world. Investigation in the IRC channel thus faces many practical issues.

MyDoom virus provides another example of building such a DoS attack network (CERT 2004). Different from botnets, the attack network was not solely built through

technological vulnerabilities. One variant of MyDoom could coax computer users into executing a malicious program that was sent either as an e-mail attachment or as a file downloaded from a peer-to-peer (P2P) network. The attacking program in compromised computers was designed to automatically and simultaneously flood toward www.sco.com on February 1, 2004, and www.microsoft.com on February 3, 2004.

Why a DoS/DDoS Attack May Succeed

The design of the Internet is one of the fundamental reasons for successful DoS attacks. The Internet is designed to run end-to-end applications. Routers are expected to provide the best-effort packet forwarding, while the sender and the receiver are responsible for achieving desired service guarantees such as quality of service and security. Accordingly, different amounts of resources are allocated to different roles. Routers are designed to handle large throughput that leads to the design of high-bandwidth pathways in the intermediate network. On the contrary, end hosts may be assigned only as much bandwidth as they need for their own applications. Consequently, each end host has less bandwidth than do routers. Attackers can misuse the abundant resources in routers for delivery of numerous packets to a target.

The control and management of the Internet is distributed. Each component network is run according to local policies designed by its owners. No deployment of security mechanisms or security policy can be globally enforced. Because DoS attacks are commonly launched from systems that are subverted through security-related compromises, the susceptibility of the victim to DoS attacks depends on the state of security on the rest of the global Internet, regardless of how well the victim may be secured. Furthermore, it is often impossible to investigate cross-network traffic behaviors in such a distributed management. If one party in a two-way communication (sender or receiver) misbehaves, it can cause arbitrary damage to its peer. No third party will step in to stop it.

The design of the Internet also hinders the advancement of DDoS defenses. Many solutions have been proposed to require routers and source networks, together with victims, to participate in constructing a distributed and coordinated defense system. However, the Internet is administered in a distributed manner. Besides the difference of individual security policies, many entities (source networks and routers) in the Internet may not directly suffer from DDoS attacks. Hence, they may not have enough incentive to provide their own resources in the cooperative defense system.

Finally, the scale of the Internet requires more effort to get a defense system benchmark and test bed to evaluate and compare proposed defense technologies. Defense systems should be evaluated with large-scale experiments, data should be collected from extensive simulations, and cooperation is indispensable among different platforms and networks. Researchers, industries, and the U.S. government are trying to develop a large-scale cyber security test bed (DETER 2005) and design benchmarking suites and measurement methods (EMIST 2005) for security systems evaluation.

TAXONOMY OF DOS/DDOS ATTACKS ON THE INTERNET

In this section, DoS attacks are classified based on the material presented by Mirkovic and Reiher (2004). Interested readers can obtain further information on DDoS attacks from Mirkovic et al.'s (2005) book. The classification is according to the major characteristics of DDoS attacks: (1) how attackers (or zombies) scan vulnerable computers, (2) how attack packets are spoofed, (3) what attack targets are, and (4) what attack impacts are.

Scanning

In the past, an attacker manually scanned remote computers for vulnerability and installed attack programs. Now, the scanning has been automated by worms (Staniford, Paxson, and Weaver 2002) to help attackers quickly probe potentially vulnerable computers. Attackers can also control the scanning behavior to find vulnerable computers in a slow and stealthy manner. Worm scanning may have secondary impacts on address resolution protocol (ARP) (CISCO 2001) and multicast (Hamadeh et al. 2005) because of high router CPU utilization and memory demand.

Random Scanning

In random scanning, each compromised computer probes random addresses in either global or local IP address space. Because scanning attempts are not synchronized among attacking hosts, there are often duplicate probes to the same addresses. Thereby, a high volume of scanning traffic may be present, especially when most of the vulnerable computers on the Internet are infected.

Hitlist Scanning

A compromised computer performs hitlist scanning according to an externally supplied list. When it detects a vulnerable computer, it sends a portion of the hitlist to the recipient. A complete hitlist allows an attacker to infect the entire susceptible population within 30 seconds (Staniford et al. 2002). Nevertheless, the hitlist needs to be assembled in advance via other reconnaissance and scanning approaches. In addition, the list might be long. Thus, the transmission of the hitlist between two hosts might create a high volume of traffic.

Signpost Scanning

Signpost scanning takes advantage of habitual communication patterns of the compromised host to select new targets. E-mail worms use the information from the address books of compromised machines for their propagation. A Web-based worm could be propagated by infecting every vulnerable client that clicks on the server's Web page. Signpost scanning does not generate a high traffic load. The drawback is that the propagation speed depends on user behavior and is not controllable by the attacker.

Permutation Scanning

This type of scanning requires all compromised computers to share a common pseudo-random permutation of the IP address space, and each IP address is mapped to an index in this permutation. Permutation scanning

Figure 5: Source-address spoofing

is preceded by a small-hitlist scanning. A computer infected in the hitlist then scans through the permutation, starting with its IP address. A computer compromised by permutation scanning starts from a random point in the permutation. Whenever a scanning host sees an already-infected machine, it chooses a new random starting point. The scanning host will become dormant to avoid collision after encountering some threshold number of infected hosts. The analysis (Staniford et al. 2002) shows that the propagation speed could be on the order of 15 minutes if a 10,000-entry hitlist is used and a worm generates 100 scans per second. As infection progresses, a large percentage of infected machines become dormant, which hinders detection because of the low duplicate scans.

Spoofing

Spoofing techniques define how the attacker chooses the spoofed source address in its attack packets. Spoofing attackers can choose one of three approaches, as depicted in Figure 5.

Random Spoofing

Attackers can spoof random source addresses in attack packets, since this can simply be achieved by generating random 32-bit numbers and stamping packets with them. Attackers may also choose more sophisticated spoofing techniques, such as subnet spoofing, to defeat some anti-spoofing firewalls and routers using ingress filtering (Ferguson and Senie 1998) and route-based filtering (Li et al. 2002).

Subnet Spoofing

In subnet spoofing, the attacker spoofs a random address within the address space of the sub-network. For example, a computer in a C-class network could spoof any address with the same prefix. It is impossible to detect this type of spoofing anywhere on the Internet. Subnet spoofing is useful for the attackers that compromise machines on networks running ingress filtering. A possible defense against this type of spoofing is to bind the IP address,

the media access control (MAC) address, and the network port of each computer in the subnetwork.

Fixed Spoofing

Different from the other two spoofing techniques, the spoofed address is the address of the target. For example, an attacker performing a smurf attack spoofs the victim's address so that ICMP ECHO packets will be reflected to the victim.

Target

Although most DoS attacks work via exhausting resources, the actual target for which to deny services varies. The target could be the server application, the network access, or the network infrastructure.

Server Application

An application attack targets a given application on the victim (normally a server), thus disabling legitimate clients to use the service and possibly tying up resources of the host machine. Nevertheless, if the victim can well separate the resources for different applications, other applications and services in the victim should still be accessible to users. For example, a signature attack on an authentication server can send a large volume of authentication requests to exhaust the victim's resources of the signature verification and thus bring down the service. Nevertheless, if the victim can separate resources for applications, the victim can still have resources for other applications that do not require authenticated access. Consequently, the victim may need to enforce defense in each application, instead of only in its network access or its operating system.

Network Access

This type of attack disables access to the victim's computer or network by crashing it or overloading its communication mechanism. An example of this type of attack is the UDP flooding attack. All attack packets carry the destination address of the target host without concerning the content of the target service. The high packet volume consumes network resources of the victim. At the same time, the attack traffic in fact facilitates detection, but the host cannot defend against these attacks alone. It must request help from some upstream routers and firewalls.

Infrastructure

Infrastructure attacks target some critical services that are crucial for global Internet operation. Examples include the attacks on domain name servers, core routers, certificate servers, etc. The key feature of these attacks is not the attack mechanism, but the attack target and the attack impact.

Impact

Depending on the impact of a DDoS attack on the victim, the attacks are classified as disruptive and degrading.

Disruptive

The objective of disruptive attacks is to completely stall or crash the victim's service. For instance, the victim

network is completely congested under attack, or the victim server crashes or halts under attack. Consequently, clients cannot access the service.

Degrading

The objective of degrading attacks is to consume some portion of a victim's resources to seriously downgrade the service performance. For example, an attack sends a high volume of authentication requests that can significantly consume computing resources in the target server. This attack can slow down the service response to legitimate customers. If customers are dissatisfied with the service quality, they may change their service provider.

DDoS DEFENSES ON THE INTERNET

In this section, we provide an overview of products that have been deployed with an emphasis on their functionalities and principles. Then, we will focus our discussion on recent defense technologies proposed by researchers, and categorize them according to where they could be deployed.

Defense Technologies in Deployment

In response to DDoS attacks, a variety of commercial products have been developed and deployed by networking and security manufacturers, mainly including intrusion-detection systems (IDSs), firewalls, and security-enhanced routers. These devices are normally deployed between the Internet and servers so that they can monitor incoming and outgoing traffic and take appropriate actions to protect servers. Fundamental technologies inside these devices include traffic analysis, access control, packet filtering, address blocking, redundancy, etc.

IDSs typically log incoming traffic and make statistics from traffic traces. For example, CISCO IOS NetFlow (2006) can account for network traffic and usage and provide valuable information about network users and applications, peak usage times, and traffic routing. Traffic traces and statistics can be compared to baseline traffic profiles to identify potential DoS attacks. In the past, most DDoS attacks caught attention because of abnormal conditions of the victim network, such as high traffic volume targeting at a certain port, slowing down of target servers, or high dropping rates of service requests. In addition, well-known DoS attack signatures (e.g., TCP SYN flooding) can also be captured to raise alerts.

Firewalls are widely deployed in the defense against DoS attacks. With correct configurations, firewalls are used to inspect ingress and egress packets and filter unwanted packets. Firewalls allow or deny certain packets according to protocols, ports, IP addresses, payloads, connection states, etc. The information is usually defined in access-control lists and filtering rules in firewalls. Some firewalls and IDSs (CISCO PIX 500 Series Security Appliances 2006; Bro 2006) can conduct stateful inspection so that only legitimate packets for ongoing connections can be passed into networks, and only legitimate TCP connections can be established and maintained. Firewalls can also create profiles (idle duration, data rate, etc.) for connections and conduct real-time analysis to detect and forbid

malicious attempts (Thomas et al. 2003). Several products (MAZU 2006, CISCO Guard DDoS Mitigation Appliances 2006) integrate intrusion detection and firewall functions, and give more DDoS-specific visibility of the network for administration. Security measures in routers can push the defense frontline further away from the target, so that internal networks will not be directly impacted by DDoS flooding traffic. Similar to firewalls, many routers have access-control lists, and can filter or rate-limit traffic. Routers can quickly filter packets having bogus and unwanted IP addresses, while firewalls can more closely examine packet payloads.

Service providers can also increase redundancy of network and service infrastructure (Handley and Rescorla 2006). Service content can be backed up in redundant servers. When a server fails, redundant servers can take it over. Failure due to DoS attacks, in this case, is the same as a regular failure. Service access points can be distributed across network as well. Since DoS attacks may target only a single network link, redundant network accesses can alternatively provide services. Nevertheless, redundancy solutions may not be as effective as expected against DoS attacks. First, redundancy asks for additional computing resources to handle incoming traffic. It could be costly for service providers to maintain enough computing resources. Second, attackers can easily find a large number of attacking agents in the Internet (refer to the section on "Attack Techniques," above) to overwhelm the capability of redundant equipments.

Although a few practical solutions and products have been deployed, many problems still exist. First, it is hard to distinguish flash crowds from flooding traffic. For example, firewalls may not prevent attacks against port 80 (Web service) of servers, because many packets are just surfing traffic to the Web sites hosted by the target servers. Second, when flooding traffic is mitigated through filtering and rate-limiting mechanisms, some portion of the legitimate traffic may also be discarded. Access-control lists may be set up on wrong information as well, because flooding packets may spoof addresses. Third, firewalls and routers can be easily overwhelmed under DDoS attack. They may be slowed down or congested. If they cannot forward incoming packets to servers, attackers also achieve DoS effects. Fourth, existing products act on their own without any control over other routers. Even if a border router or firewall has identified the upstream routers from which flooding packets are coming, it is not easy to ask the owners of upstream routers (e.g., telecom companies or Internet service providers) to throttle some specific traffic flows. Observing these problems, researchers have proposed quite a few DDoS defense technologies. In the following, we present them according to the location where they could be deployed.

Attacker-Side Defenses

Since source address spoofing plays an important role in DDoS attacks, restricting the source address of the traffic to known prefixes is a straightforward idea. Ingress filtering is a representative technique (Ferguson and Senie 1998) based on this idea. As depicted in Figure 5, an attacker resides within a C-class network 152.152.152.0/24.

The gateway of the network, which provides connectivity to the attacker's network, allows only traffic originating from source addresses with the 152.152.152.0/24 prefix, while prohibiting an attacker from using "invalid" source addresses that reside outside this prefix range (e.g., 192.100.201.20). This technique can well prevent random address spoofing and fixed address spoofing. The idea of filtering packets according to their source addresses is also applicable in Internet routers (Li et al. 2002; Park and Lee 2001). SAVE (Li et al. 2002) enforces routers to build and maintain an incoming table for verifying whether each packet arrives at the expected interface. Obviously, ingress filtering does not preclude an attacker using a forged source address of another host within the permitted prefix filter range (i.e., subnet address spoofing). Nevertheless, when an attack of subnet address spoofing occurs, a network administrator can be sure that the attack is actually originating from within the known prefixes that are being advertised.

D-WARD (Mirkovic, Prier, and Reiher 2002) is another technique on the attacker side that prevents the machines from participating in DDoS attacks. D-WARD monitors two-way traffic between the internal addresses and the rest of the Internet. Statistics of active traffic are kept in a connection hash table and compared to predefined models of normal traffic, and noncomplying flows are rate-limited. The imposed rate limit is dynamically adjusted as flow behavior changes, in order to facilitate fast recovery of misclassified legitimate flows and severely limit ill-behaved aggressive flows that are likely to be a part of an attack. Because of the limited size of the hash table, D-WARD can possibly discard packets of legitimate traffic during a DDoS attack in which many malicious flows are present. D-WARD also needs to be able to monitor traffic in both incoming and outgoing directions, which may be not realistic when a network has several border routers. D-WARD, similar to other attacker-side defense systems, can limit attack traffic only from the networks from which it is deployed. Attackers can still perform successful DDoS attacks from networks that are not equipped with the D-WARD system. Because attacking sources are randomly distributed, it is thus necessary to deploy attack-side defense systems in as many networks as possible so that DDoS attacks can be fully controlled at the source.

Victim-Side Defenses

Many defense systems are proposed at the victim side (Gil and Poletter 2001, Wang, Zhang, and Shin 2002) since victims suffer the greatest impact of DoS attacks and are therefore most motivated to enforce defenses. Jin, Wang, and Shin (2003) proposed hop-count filtering based on the observation that most randomly spoofed packets do not carry hop-count values that are consistent with the spoofed addresses. Thereby, time-to-live (TTL) value in packets can be used to decide if a packet is spoofed. A router decreases the TTL value of an in-transit IP packet by one before forwarding it to the next-hop. The final TTL value when a packet reaches its destination is the initial TTL subtracted by the number of intermediate hops (i.e., hop-count). However, the final TTL value that the destination can see does not directly reveal the hop-count. Fortunately, most

modern OSs use only a few selected initial TTL values—30, 32, 60, 64, 128, and 255. This set of initial TTL values covers most of the popular OSs, such as Microsoft Windows, Linux, BSD, and many commercial Unix systems. In addition, few Internet hosts are apart by more than 30 hops (Cheswick, Burch, and Branigan 2000). Hence, one can determine the initial TTL value of a packet by selecting the smallest initial value in the set that is larger than its final TTL. For example, if the final TTL value is 112, the initial TTL value is 128 (i.e., the smaller one of the two possible initial values, 128 and 255). A hop-count filtering system first builds an IP-to-hop-count mapping table, and clusters address prefixes based on hop-count. With the table, the system works in two running states: alert and action. Under normal condition, the system stays in alert state, watching for abnormal TTL behaviors without discarding any packet. Even if a legitimate packet is incorrectly identified as a spoofed one, it will not be dropped. Therefore, there is no collateral damage in the alert state. Upon detection of an attack, the system switches to action state, in which the system discards IP packets with mismatching hop-counts. The inspection algorithm extracts the source IP address and the final TTL value from each IP packet. The algorithm infers the initial TTL value and subtracts the final TTL value to obtain the hop-count. The source IP address serves as the index into the table to retrieve the correct hop-count for this IP address. If the computed hop-count does not match the stored hop-count, the packet is classified as spoofed.

Hop-count filtering cannot recognize forged packets whose source IP addresses have the same hop-count value as that of a zombie, a diverse hop-count distribution is critical to effective filtering. Jin et al. (2003) found that the Gaussian distribution is a good first-order approximation. The largest percentage of IP addresses that have a common hop-count value is 10 percent. The analysis using network measurement data shows that hop-count-filtering can recognize nearly 90 percent of spoofed IP packets. The stability in hop-counts between a server and its clients is also crucial for hop-count filtering to work correctly and effectively. Frequent changes in the hop-count between the server and each of its clients can lead to excessive mapping updates. Paxson (1997) found that the Internet paths are dominated by a few prevalent routes, and about two thirds of them have routes persisting for either days or weeks. Jin et al. (2003) also made measurements and found that 95 percent of paths had fewer than five observable daily changes. Hence, the hop-count filtering approach needs to update the IP-to-hop-count mapping table daily. Hop-count filtering is designed to filter spoofed packets. It does not prevent an attacker from flooding packets with true sources and correct TTL values. Hence, it cannot protect victims from recent DDoS attacks using bots that do not necessarily spoof source addresses.

Defenses in Transit Networks

DDoS defense mechanisms deployed at the intermediate network provide infrastructural defense to a large number of Internet hosts. They usually ask routers to collaboratively monitor and exchange certain information to defend against DDoS attacks. Distributed congestion

puzzle (Wang and Reiter 2004), pushback (Mahajan et al. 2002, Ioannidis and Bellovin 2002) and traceback (Yaar, Perrig, and Song 2005; Savage et al. 2000; Snoeren et al. 2001), and capability filtering (Anderson et al. 2003, Yaar, Perrig, and Song 2004; Yang, Wetherall, and Anderson 2005) techniques are representative intermediate network mechanisms.

Defenses Using Puzzles

Client puzzles have been proposed to defend against DoS attacks in TCP (Juels and Brainard 1999), SYN cookie (Bernstein 1996), authentication protocols (Aura, Nikander, and Leiwo 2000), TLS (Dean and Stubblefield 2001), graphic Turing test (Kandula et al. 2005), application traffic control (Walfish et al. 2006), etc. In brief, when a client requests a service, the server first asks the client to solve a problem before accepting the service request. Then, the client needs to send an answer back to the server. Usually, solving the problem takes a certain amount of computing resources, while resource demand for verifying an answer is negligible. The server will discard service requests if either the client does not reply or the answer is incorrect. Most of these protocols involve only clients and servers in the puzzle-solving mechanisms. In contrast, Wang and Reiter (2004) proposed a distributed puzzle mechanism (DPM) to defend against bandwidth-exhaustion DDoS attacks in which routers take the main role in solving puzzles and verifying puzzle solutions. In DPM, a typical puzzle is composed of a moderately hard function (such as hash function MD5); solving the puzzle requires a brute-force search in the solution space. The hash takes three parameters: a server nonce N_s created by the congested router, a client nonce N_c created by the client, and a solution X computed by the client. The solution of the puzzle satisfies that the first d bits of $h(N_s, N_c, X)$ are zeros. d is called the puzzle difficulty. DPM requests routers on the puzzle distribution paths to generate their own path nonces and attach them to the congestion notification during the puzzle distribution phase. By using path nonces, DPM gives different responders different puzzles (nonce sequences), thus preventing the adversary from replaying the solutions via different paths. For example, in Figure 6, R2 and R3 treat $N_s N_1$ as the server nonce and append their own nonces to the nonce sequence; R1 treats $N_2 N_a$ and $N_3 N_b$ as the client nonces from R2 and R3. Once a link adjacent to a router is congested, the router requires the clients to solve the puzzle and thereby imposes a computational burden on clients who transmit via this router. The computation demand is tied to the bandwidth consumed by a puzzle-based rate-limiter implemented in the router.

DPM requires a participating router to keep puzzles for a period to verify solutions and prevent reusing puzzles. Hence, it might be demanding for a high-throughput router to be equipped with a large memory for keeping nonces and a fast CPU for verifying solutions. Probabilistic verification is applied to reduce the computational load of verification. Based on the arriving packet rate, a DPM router dynamically adjusts the sampling rate to selectively verify solution packets and prevents the router's CPU from being overloaded. In addition, a DPM router uses bloom filters to reduce the memory demand from 80 MB to 1 MB. Although DPM distributes computation

Figure 8: FIT packet marking

TTL in the distance field b . Yaar et al. (2005) shows that $c = 22$ is the best parameter for traceback. This last step allows the next FIT-enabled router, or the packet receiver, to determine the distance from the router's mark.

In FIT, an end host first computes hashes of all IP addresses, which can be done in hours. Then, the end host obtains distances and IP hashes of upstream routers from marked packets. Therefore, the end host can set up a table (map) of IP, hash, and distance of upstream routers. The map is normally constructed prior to the attack and updated according to normal incoming traffic. When an attack occurs, the end host obtains the hash segment and the distance from a marked packet to determine from which router the packet comes. FIT uses node marking instead of the commonly used edge marking (Dean et al. 2002; Savage et al. 2000; Snoeren et al. 2001). Hence, FIT avoids incrementally reconstructing the attack paths. Node marking also enables the end host to reconstruct the attack paths from much fewer packets (hundreds in contrast to thousands in edge marking). Furthermore, an FIT router does not require the next router to be an FIT router. Therefore, FIT is an incrementally deployable scheme. However, FIT does not stop an ongoing attack. When true attacking sources are identified, attacking traffic should be filtered. At the victim side, it is impossible to filter attacking packets, because they may not carry true sources. Hence, victims will need to ask routers closing to the true attacking sources to filter the attacking traffic or stop attacking hosts. Unfortunately, such a counterattack would need a complex and coordinated defense system deployed throughout the Internet.

Capability Filtering

The design principles of the Internet overlooked the receivers' capability. In many cases, routers are designed to forward packets from senders, regardless of whether or not the packets are desired by receivers. Although several aforementioned approaches (Mahajan et al. 2002; Argyraki and Cheriton 2005; Li et al. 2002) have been proposed to filter unwanted packets at upstream routers before they can consume the resources of destinations, these approaches act without knowing the allowance of destinations. As a consequence, these approaches may block legitimate traffic, because routers cannot discriminate attacking traffic from other traffic, especially when attackers can compose packets with contents of their choosing. To solve this problem, researchers proposed the approach of putting a token of capability into each data packet to prove that packets were requested by receivers (Anderson et al. 2003; Yaar et al. 2004; Yang et al. 2005). This category of filtering approaches takes two steps. First, a sender requests permission to send; after verifying the sender is valid, the receiver

provides a token of capability. Then, routers along the path from the sender to the receiver can verify packets carrying the token and forward the packets with valid tokens.

In the first step (capability handshake), capabilities are obtained using request packets that do not have capabilities. A request is sent as a part of the TCP SYN packet. If the request is authorized, a token of capability is piggybacked in the TCP SYN/ACK packet. Thereby, routers are also notified of the capability. Once the sender receives the capability, the communication is bootstrapped. To identify paths, each router at the ingress of a trust boundary tags requests with a unique value (flow nonce) derived from its incoming interface. Routers not at trust boundaries do not tag requests, but fair-queue requests using their tags as unique path identities. Thereby, an attacker that composes arbitrary requests can, at most, cause contention in one queue that is corresponding to the edge router of the attacker. At the same time, request packets compromise only a small fraction of traffic. Hence, it is difficult for attackers to manipulate the capability handshake step.

Capability is bound to a specific network path, including source and destination addresses, in a specific duration. Each router that forwards a request packet generates its own precapability and attaches it to the packet. The precapability consists of a time stamp and a cryptographic hash of the time stamp, the source and destination IP addresses, and a secret known only to the router. Each router can verify for itself that a purported precapability attached to a packet is valid by recomputing the hash. The precapability is hard to forge without knowing the router secret. The destination receives an ordered list of precapabilities that corresponds to a specific network path with fixed source and destination IP end points. The destination adopts fine-grained capabilities that grant the right to send up to N bytes along a path within the next T seconds. The destination converts the precapabilities it receives from routers to full capabilities by hashing them with N and T . If the destination wishes to authorize the request, it returns the ordered list of full capability, together with N and T , to the sender. Routers along the path verify their portion of the capabilities by recomputing the hashes and the validity of time. Routers cache their capabilities and the flow nonce for verification later. For longer flows, senders should renew these capabilities before they reach their limits. Finally, all packets carry a capability header that is implemented as a shim layer above IP so that there are no separate capability packets. Regular packets have two formats: packets that carry both a flow nonce and a list of valid capabilities and packets that carry only a flow nonce. A regular packet with a list of capabilities may be used to request a new set of capabilities. A few problems might exist because of the dynamic nature of the Internet. First, routes could change. Packets in this case are handled by demoting them to low priority as legacy traffic. These packets are likely to reach the destination only when there is little congestion. Second, routes could be asymmetric, and thus capability handshake cannot be achieved and communication cannot be established. Third, the approach is not applicable when partially deployed on the Internet, because a router without implementing capability filtering still forwards as many packets as possible.

Figure 9: Architecture of DefCOM

Defenses Using Overlay Networks

Aforementioned defense technologies require homogeneous system design. However, no single defense mechanism can guarantee wide deployment, as deployment depends on market conditions and social aspects. Therefore, Mirkovic et al. (2003) proposed defensive cooperative overlay mesh (DefCOM) as a new deployment paradigm, which uses a peer-to-peer network to integrate heterogeneous systems. Nodes in DefCOM are classified as three types: alert-generator nodes that detect attacks and deliver attack signatures to the rest of the peer network; core nodes that rate-limit high-volume transit traffic-matching signatures; and classifiers that perform selective rate-limiting, differentiate between legitimate flows and attack flows, and cooperate with other defense nodes to ensure preferential service for legitimate traffic. As demonstrated in Figure 9, alert-generator node R0 detects a DDoS attack on the victim, and informs all other defense nodes through the DefCOM network. The notified nodes then identify the upstream-downstream relationship between peers and cooperate to trace out the topology of the victim-rooted traffic tree. Knowing the tree, the classifiers can differentiate legitimate traffic from attack streams and devise the appropriate rate limits to restrain the attack traffic. DefCOM allows heterogeneous systems to cooperate to achieve a better overall defense, instead of every defense system operating in isolation. Each system would autonomously perform the defense functions that it is best at and compensate for its weaker traits through cooperation with other systems. Division of work would enable nodes to become more specialized, leading to better overall performance. The wide deployment necessary to handle diffuse attacks would be achieved by incorporating existing defense nodes in the framework. As the attacks evolve, new systems could join and either replace or enhance the functionality of the old ones. Nevertheless, the design of interface in the overlay network for different defense systems to cooperate is still open.

Overlay network also provides an infrastructure to deploy distributed DDoS defense system. Secure overlay services (SOS); (Keromytis, Misra, and Rubenstein 2004) prevents DoS attacks on critical servers via an

overlay network. In general, a defense system, such as a firewall, should be able to filter malicious traffic. To avoid the effects of a DoS attack against the firewall connectivity, expensive processing tasks of a firewall, such as access control and cryptographic protocol handling, are distributed to a large number of nodes in an overlay network. Thus, SOS becomes a large distributed firewall that distinguishes “good” (authorized) traffic from “bad” (unauthorized) traffic. Service requests from authenticated clients are routed to the protected servers via the overlay network, while nonauthenticated requests are filtered. Mayday (Andersen 2003) generalizes the idea of SOS and uses a distributed set of overlay nodes that are trusted (or semi-trusted) to distinguish legitimate traffic from attack traffic. To protect a server from DDoS traffic, Mayday prevents general Internet hosts from communicating directly with the server by imposing a router-based, network-layer filter ring around the server. Clients communicate with overlay nodes that verify whether a client is permitted to use the service. These overlay nodes then use an easily implemented lightweight authenticator to get through the filter ring. Within this framework, SOS represents a particular choice of authenticator and overlay routing, using distributed hash table lookups for routing among overlay nodes and using the source address of the overlay node as the authenticator. Since these overlay-based defense techniques work at the application layer, their deployment requires client systems to modify the access model of applications so that client systems are aware of the overlay and use it to access the target.

DOS ATTACKS AND DEFENSES IN WIRELESS NETWORKS

Wireless networks are taking a more important role today. As these networks gain popularity, providing security and trustworthiness will become an issue of critical importance. In this section, we discuss DoS attacks and defense in wireless networks according to the three lower network layers. Attacks at and above the transport layer in wireless network are similar to attacks on the Internet. Note that our focus is on IEEE 802.11-based wireless networks, which is a family of physical and MAC protocols used in many hotspot, ad hoc, and sensor networks.

Physical-Layer Attacks and Defenses

The shared nature of the wireless medium allows attackers to easily observe communications between wireless devices and launch simple DoS attacks against wireless networks by jamming or interfering with communication. Such attacks in the physical layer cannot be addressed through conventional security mechanisms. An attacker can simply disregard the medium access protocol and continually transmit in a wireless channel. By doing so, the attacker either prevents users from being able to commit legitimate MAC operations or introduces packet collisions that force repeated backoffs. Xu et al. (2005) studied four jamming attack models that can be used by an adversary to disable the operation of a wireless network and observed that signal strength and carrier sensing time are unable to conclusively detect the presence of

a jammer. It is also found that the packet-delivery ratio may help differentiate between congestion and jamming scenarios but cannot help defenders to conclude whether poor link utility is due to jamming or to the mobility of nodes. To address the jamming attacks, Xu et al. (2005) proposed two enhanced detection protocols. One scheme uses signal strength measurements as a reactive consistency check for poor packet-delivery ratios, and the other uses location information to serve as the consistency check.

MAC-Layer Attacks and Defenses

In the MAC layer, the defects of MAC protocol messages and procedures of a MAC protocol can be exploited by attackers. Bellardo and Savage (2003) discussed the vulnerabilities of authentication and carrier sense and showed that attackers can provide bogus information or misuse the carrier sense mechanism to deceive normal nodes. For example, attackers can forge deauthentication or disassociation packets to break the connections between nodes and access points or send ready-to-send (RTS) and clear-to-send packets with a forged duration to suppress the transmission of nearby nodes. Attackers can disobey the backoff procedure so that they always get the first chance to send RTS right after the end of last transmission. Gu, Liu, and Chu (2004) analyzed how the attackers can exhaust bandwidth by using large junk packets without breaking the MAC protocol. The attackers can use certain packet generation and transmission behavior to obtain more bandwidth than other normal nodes. Wullems et al. (2004) identified that attackers can exploit the Clear Channel Assessment function of the 802.11 protocol to suppress other nodes with the illusion of a busy channel. Bellardo and Savage (2003) suggested that extending explicit authentication to 802.11 control packets would be a solution to prevent attackers from easily forging the protocol control packets.

Networking-Layer Attacks and Defenses

DoS attacks in the network layer focus mainly on exploiting routing and forwarding protocols in wireless networks. In particular, ad hoc and sensor networks are susceptible to these attacks. It is also noticed that network-layer DoS attacks on wireless networks are very different from the attacks in the Internet. Because routers in wireless networks are computers that could be compromised as end hosts, network-layer DoS attacks in wireless networks can be launched by any computer in the network. In addition, DoS defense techniques on the Internet that demand the cooperation of routers are no longer valid.

Routing Attacks and Defenses

Researchers have shown that attackers can manipulate ad hoc network routing protocols (such as DSR [Johnson, Maltz, and Hu 2002] and AODV [Perkins, Belding-Royer, and Das 2002]) to break valid routes and connections (Hu, Perrig, and Johnson 2002, 2003). For example, if attackers change the destination IP address in the route request message, the victim cannot establish a route to its destination and thus cannot access services. Hence, the

security of routing protocols is the solution for defending routing-based DoS attacks. In order to prevent attackers from exploiting the security flaws in routing protocols, several secure routing protocols have been proposed to protect the routing messages and thus prevent DoS attacks. For example, Hu et al. (2002) proposed to use TESLA (Perrig et al. 2002), which is a symmetric broadcast-authentication protocol, in routing discovery to secure routing protocols. When a source sends a route request, it authenticates the request with its own TESLA to prevent attackers from forging or modifying the request.

Forwarding Attacks and Defenses

Similar to routing attacks, attackers can also exploit forwarding behavior. Typical attacking approaches include injecting junk packets, dropping packets, and disorder packets in legitimate packets. Attackers can use spoofed packets to disguise their attacking behavior, or find partners to deceive defenders. The objective is to exhaust bandwidth (Gu et al. 2005) or disrupt connection (Aad, Hubaux, and Knightly 2004) so that service cannot be delivered.

To prevent attackers from spoofing and flooding packets in wireless networks, hop-by-hop source authentication is needed so that every node participates in the protection of the network. Ye et al. (2004) proposed a statistic filtering scheme that allows en route nodes to filter out false data packets with some probability. This approach will not filter packets that do not carry keys that the en-route nodes have, but will discard them at the destination. Zhu et al. (2004) proposed an interleaved hop-by-hop authentication scheme that guarantees that false data packets will be detected and dropped within a certain number of hops, although the scheme does not tolerate the change of routers. Gu et al. (2005) proposed another hop-by-hop source authentication approach with a higher overhead to ensure that a packet can be verified when a route is changed because of unreliability in wireless networks. In this approach, the routing node at which a new route diverges from the old route takes the responsibility of authenticating the packets. The routing nodes in the new route can then verify the packets based on the new authentication information.

CONCLUSION

In this chapter we presented an overview of existing DoS attacks and defense technologies on the Internet and on wireless networks. DoS attackers exploit flaws in protocols and systems to deny access of target services. Attackers also control a large number of compromised hosts to launch DDoS attacks. Simply securing servers is no longer enough to make service available under attack, since DoS attack techniques are more complicated and many unwitting hosts are involved in DoS attacks. By reviewing several existing DoS attack techniques and classifying them, this chapter highlighted challenges of DoS defense from characteristics of DoS attacks. For defenders, it is difficult to decide whether a packet is spoofed, to prevent a host from being compromised and controlled, to ask upstream

routers to filter unwanted traffic, and to keep defenders themselves from DoS attacks.

This chapter reviewed current DoS defense solutions in deployment and in research. These solutions are trying to address one or several problems in DoS defense, for instance, how to distinguish legitimate traffic from flooding traffic, how to identify or trace true attacking hosts, how to filter or control flooding traffic as close as possible to attacking sources, and how to allow routers to collaborate in defense. These solutions can handle some but not all DoS attacks because of their design principles, deployment issues, etc. New DoS attack techniques may also invalidate these solutions. This chapter acknowledged these innovative ideas and provided a fundamental understanding for developing new solutions.

Different from the Internet, wireless networks have their own unique DoS attacks because wireless is an open communication approach and mobile devices can function as routers in wireless networks. DoS attacks in wireless networks extend to a scope not viable on the Internet. The existing defense approaches illustrate that security countermeasures should be studied and incorporated into wireless protocols at lower layers, and mobile hosts should actively and collaboratively participate in protecting their wireless networks.

GLOSSARY

Access control: A range of security methods to permit or deny the use of an object by a subject. An object refers to a resource in a system. A subject refers to an entity that performs actions. Access control methods decide whether a subject can access an object based on the subject's identity and a predefined access control matrix.

Ad hoc network: A type of network that does not have an infrastructure. Normally, a host in the network should forward packets as a router even though the packets are neither originated nor destined to the host. The host can also ask other hosts to forward its packet via routing protocols.

Bot: A type of malicious program that functions as a backdoor in the host and accepts commands from its master. It is more organized than other malicious programs in that many bots often form a network via certain communication mechanisms. Such a network is called BotNet.

CTS: In an 802.11 network, a receiving computer sends a clear-to-send (CTS) packet to a sending computer to indicate the shared wireless channel is cleared for transmission and inform all other computers in the receiver's transmission range to suspend transmission to avoid collision.

DoS: A type of attack that targets disabling service, denying service access, or downgrading service performance. DoS attack techniques vary as long as the attack objective can be achieved. Many recent DoS attacks try to exhaust resources for providing services.

MD5: A cryptographic hash function designed by Ronald Rivest in 1991. The algorithm processes a variable-length message and generates a fixed-length hash output of 128 bits.

Overlay Network: A network that runs above the network layer and consists of end hosts forwarding packets as routers. The underlying communication between end hosts is unicast, even when an end host communicates with several other end hosts. The network is normally application-oriented.

RSA: A public key encryption/decryption algorithm invented by Ron Rivest, Adi Shamir and Leonard Adleman in 1977. RSA are the initials of their last names.

RTS: In an 802.11 network, a sending computer sends a ready-to-send (RTS) packet to inform a receiving computer that a data packet is ready for transmission. The RTS packet is used for competing the wireless transmission channel that is shared with other computers.

Scan: In a network, scanning refers to a technique in which a computer sends a number of packets with various destination addresses and then gathers information of computers at the destination addresses according to received response packets.

Spoof: A technique to replace the originator's identity with another identity. Normally, in a network attack, an attacker puts another (any) address as the source address field in the IP header of an attack packet.

TTL: Time-To-Live field in the IP header of a packet. It is decremented by a router when the packet goes through it. It is used to prevent the packet from staying forever in the Internet because the packet will be discarded when its TTL is reduced to 0.

Worm: A type of malicious program that can be propagated by itself from one infected host to another vulnerable host. When a host is infected by a worm, the worm starts to scan other vulnerable hosts. Once a vulnerable host is found, it compromises the host by exploiting the vulnerability, and copies its code to the host. Then, the worm in the new infected host starts its own propagation.

INTRODUCTION

The classic IT (Information Technology) security tripod model (integrity, confidentiality, and availability) applies as much to e-mail as it does to other areas of information management, and the medium is subject to a range of security problems. Johnson (2000) categorizes these as follows:

- Eavesdropping (susceptibility to network sniffing and other breaches of confidentiality)
- Impersonation/Identity Theft. Even though well-managed organizations use authentication to regulate access to services, many e-mail-related Internet services such as Simple Mail Transfer Protocol (SMTP) are highly vulnerable to abuses such as impersonation by forging e-mail headers. Although identity theft is an ongoing and increasing problem, the rather less glamorous problems of impersonation by spam, fraudulent e-mail such as phishing, and malware remain a constant drain on resources and patience.
- Denial of service (DoS), either by deliberate action such as e-mail traffic volume attacks (mail bombing and subscription bombing, for example) or as an accidental result of inappropriate action by legitimate software or authorized users (mail loops, poorly configured filters, inappropriate mass mailing), or incidental action such as direct harvesting attacks (DHA) by spamming software. In the latter case, the intention is not normally to bring down systems deliberately, but the sheer volume of traffic may result in unavailability of services. At times, of course, there might be an intention to mount a secondary DoS attack from compromised systems, such as distributed denial of service (DDoS) attacks, often on sites with high profiles and low popularity: the W32/MyDoom@mm (Novarg) virus, for instance, attempted to launch attacks from infected machines on a number of vendor sites, including Microsoft and SCO (F-Secure 2004), and attacks on anti-spam sites are commonplace (Hypponen 2003).
- Overzealous Domain Name System (DNS) blacklists (or blocklists or poor practice in the use of such blacklists

by end-sites) constitute a significant problem, amounting to a denial of e-mail service on some sites. Blacklists are a primitive form of reputation service (Harley 2006). IP addresses or ranges appear in such lists on a range of criteria: for instance, known open relays, known open proxies, sites deemed not to be compliant with RFCs (Requests For Comment), and so forth. Many sites block mail from any IP address found on blacklists to which they subscribe. However, while some blacklists are professionally conceived and administered, others are run by amateurs and vigilantes who have no particular incentive to take into account high volumes of false positives. One blacklist, for instance, has included all German addresses with a .de suffix for over a year, and has refused to address the problem. Use of professional and well-conceived blacklist and reputation services reduces the problem, but some sites continue to prefer a free service, even one with a high volume of false positives.

- System integrity may be impaired in a number of ways by e-mail attacks, notably by the transmission of and subsequent or consequent infection by malicious software.

Johnson (2000) describes a number of technologies, such as encryption, authentication, anonymity protocols, and technologies that are considered elsewhere in this book. In this overview chapter, however, we deal primarily with technologies that address direct e-mail abuse such as malicious software and spam.

SOCIAL AND ANTISOCIAL E-MAIL ISSUES

As Michel Kabay (1996) points out, there are also a number of social issues associated with e-mail use and management:

- “Flaming” (intemperate language in the heat of the moment), inappropriately targeted humor or vulgarity, gossip and other indiscretions can result in bad feeling, communications breakdowns, and even implication of the employer in libel action.

- Careless targeting of e-mail responses can result in inappropriate leakage of confidential and/or sensitive information inside and beyond the organization's perimeter.
- Relations between the employer and the employed can be damaged by unclear policies and perceived rights to individual privacy.
- End users can send unconsidered mail that puts them in breach of copyright, data protection, and other legislation that restricts how data can be used and re-used.

Many of these problems are best dealt with on a policy level, and we include a consideration of e-mail-related policy management at the end of the chapter.

Malware

A full taxonomy of malware (*Malicious software*) types is beyond the scope of this chapter, which considers them only in the context of e-mail transmission. Fuller taxonomical issues are addressed by Harley, Slade, and Gattiker (2001), while Thompson (2002) and Szor (2005) address specific virus taxonomies. Other chapters in this book also deal at length with other malware issues.

E-Mail and Early Viruses

Although e-mail as a virus vector is most popularly associated with recent mass mailer epidemics, viruses have actually been associated with e-mail almost since the first replicative malware.

Boot Sector Infectors (BSIs)

Most of the effective early viruses were boot sector infectors and master boot record (MBR) infectors. Some of these are still occasionally reported; however, they do not normally spread via e-mail, but when a system is booted with an infected diskette. However, it is possible to transport such viruses in dropper form or as a disk image. These methods are normally associated with intentional transfer by mutual consent, but it is not impossible or unknown for malware to use them as a direct propagation channel.

File Viruses (Parasitic Viruses)

File viruses infect files by attaching themselves to them in some way, so that when the file is run, the virus code is also run. They are far less common than in the early days, but are still found in the wild, and can be spread by e-mail. An interesting phenomenon sometimes reported is the infection of a modern mass mailer virus/worm by an older parasitic virus such as W95/CIH, perhaps better known but misleadingly renamed as Chernobyl (Symantec 2004). (There is no evidence that the date of activation of some variants is intended to coincide with the anniversary of the Chernobyl disaster.) Some types of virus such as companion viruses and cluster viruses use somewhat different infection mechanisms, but the precise mechanics need not concern us here.

File and Boot (Multipartite) Viruses

File and boot viruses, since they use both methods of infection, in many cases can, in principle, be spread by e-mail. These are often referred to as multipartite viruses,

though strictly speaking this term refers to a virus that uses more than one infection method, and is not restricted to viruses that infect program files and boot sectors only (Harley et al. 2001).

Macro Viruses

Macro viruses normally infect documents: technically, they might be regarded as a special case of file virus. Most macro viruses infect Microsoft Word or Excel documents, but there are other vulnerable applications, not all of which are Microsoft Office applications. They can be multiplatform—most of the very few viruses to cause problems on Macintoshes in recent years have been macro viruses rather than Macintosh-specific malware (Harley 1997)—and some can affect more than one application. Macro viruses are particularly likely to be a problem in relation to applications that, like most Microsoft Office applications, store macros in data files rather than in separate macro files. Macro viruses are still commonly found transmitted by e-mail, but are much less prevalent than they were in the mid-to-late 1990s. However, it has been reported that targeted Trojan attacks of the kind reported in several CERT/CC advisories (CPNI 2005) frequently use attached Word documents containing malicious embedded executables.

Script Viruses

Script viruses are self-contained mini-programs in VB-script, Javascript, and so on, and are often found as embedded scripts in some form of HTML (HyperText Markup Language) file (as well as in some types of formatted e-mail). They may also be transmitted as e-mail attachments.

Mass Mailers

Mass mailers are a class of malware designed explicitly to spread via e-mail that maximize their own spread by seeking new target addresses from a victim's address book, files on an infected system, and other sources such as Web pages; these are considered at length below. They generally rely on social engineering (a term applied to a variety of attacks exploiting human weakness and gullibility rather than technological loopholes) to persuade the recipient to execute the malicious program. Recent examples of social engineering in mass mailer dissemination are included in the next section, and involve a form of impersonation on the part of the virus (the real sender of the e-mail) to dupe the recipient into thinking the attachment is safe to open, or at least interesting enough to be worth the risk.

Nearly all recent mass mailers are spoofing viruses: that is, they forge e-mail headers.

Spoofing Viruses

The term *spoofing* was formerly applied to viruses that exploit a characteristic of an antivirus program so as to hide their presence from that program. The term is now more often applied to e-mail viruses/worms that forge message headers (especially the "From:" and "Reply-to:" fields) to obscure the real source of the viral e-mail, or to dupe the recipient into running the viral attachment. The term is often abbreviated to *spoofers*, and the antonym is

non-spoofers or non-spoofing viruses. Spoofing viruses often insert addresses they find in the Windows address book or elsewhere on the infected hard disk, or an address from a list carried in the body of the virus, or an address simply made up. Thus, the message arrives looking as if it were sent by person A, when it really comes from person B. This not only causes mischief by blaming the wrong person for having an infected PC, it also makes it harder to trace the owner of the system that is *really* infected. Sometimes, though, a different form of spoofing is used. A popular alternative form is for the message to masquerade as a message from a vendor (especially Microsoft!) or a system administrator, passing off the attachment as a systems or application patch, or as an important message. Yet another alternative is to disguise the message as being from someone the recipient does not know and being intended for a completely different recipient, but suggesting that the content of the attachment is something particularly interesting or desirable. Popular forms of this particular trick include suggesting that the attachment consists of erotic photographs. It may also be suggested that the attachment is a returned message from the targeted recipient to the apparent, or that it contains information pertaining to their being investigated by a law enforcement agency, or a photograph of themselves, or password information, or a mail message to them received in error by the apparent sender. Although anti-virus vendor sites such as www.f-secure.com/v-descs/ (F-Secure), <http://vil.nai.com/vil/> (McAfee/AVERT), and <http://securityresponse.symantec.com/> (Symantec) include information about specific forms of message used by individual mass mailers such as Sobig, MyDoom, Bagle, and Netsky in order to trick the recipient into opening the attachment, it is not feasible to address all the possible social engineering tricks available to an imaginative writer of viruses and other malware.

"Traditional" mass mailers have declined in numbers in recent years. Indeed, replicative malware in general has declined in volume and impact since the beginning of the twenty-first century (Mashevsky 2005). In part, this is a consequence of the general professionalization of virus writing. Malicious software in general has become less the province of the "hobbyist" coder. Instead, it has become a major addition to the arsenal of the professional cyber-criminal. However, this class of malefactor is less likely to make use of the "pure" mass mailer, intended merely to self-propagate. Instead, mass mailers are used as a means of disseminating other malware, for example by installing other malicious programs on a compromised system, or by opening a channel between the compromised system and a system hosting such programs. Such a system might be a malicious Web site or another compromised system, for instance one of the bot-infested machines on a botnet. Although botnets are not wholly or even primarily an e-mail security issue, they certainly affect messaging across several dimensions, and are discussed later in this chapter.

Network Worms

Network worms are usually distinguished from e-mail viruses, as well as from conventional viruses, by the fact that they do not attach themselves to a legitimate program, though they do replicate across networks. However, this

distinction is somewhat contentious. Network worms are usually self-launching—they do not require direct user action in order to execute—and do not spread by e-mail, or not only by e-mail. (Network worms that also spread by e-mail would be better described as hybrid.) Examples include the Code Red family, Slammer, Blaster, and Welchia/Nachi. Mass mailers are also frequently referred to as worms, but are not usually self-launching, though some e-mail viruses do exploit misconfigured or unpatched mail software to execute without direct human intervention. They are, however, usually nonparasitic—that is, they do not attach to other programs, in the sense that file viruses do.

Hybrid and Multipolar Malware

Although Nimda is sometimes taken to be part of the Code Red family, it is actually a hybrid virus, a network worm that can also be spread by e-mail. Malware like this, combining multiple attack vectors, is sometimes referred to as convergent, blended, or multipolar (Harley 2002, *The future of malicious code*). Blended threats are a major factor in the current spread and impact of bots and botnets.

E-Mail Viruses and Worms

Most mass mailers—the type of virus most commonly encountered currently in the context of e-mail—occupy somewhat fuzzy middle ground between conventional viruses (because they replicate), worms (because they do not attach themselves to a legitimate program), and Trojans (because they trick the recipient into running malicious programs, thinking they do something desirable). In fact, there can be considerable overlap between these types. (Trojans are considered in more detail below.) Melissa, for example, was a macro virus but also one of the first effective e-mail worm/mass mailers (though claims that it was *the* first are untenable). It tricked the recipient into opening a document that then ran code, much as the CHRISTMA EXEC worm had in 1987 (Slade 1996). It infected other documents (and so can be described as a true virus), but also made use of e-mail to trick the recipient into furthering its spread. More recent mass mailers tend to rely on persuading the victim to run stand-alone code, but some also use software vulnerabilities as an additional entry point, and some mass mailers are also viruses, or drop viruses or other malware—especially Trojans such as keyloggers and backdoors—as part of the replicative mechanism.

The mass mailer problem has been seriously compounded by the poor option sets or local configuration of some filtering and antivirus products and services, especially gateway products. There are many circumstances under which generation of multiple alerts or any alert at all is incorrect behavior, most notably when the message that accompanies a mass mailer is known to forge message headers. An infected message should be returned to the sender only if it can be ascertained with reasonable certainty that the address in the From: and Reply-To: fields is not forged. Even then, it should not be returned with the uncleaned attachment, as often happens with filters that do not recognize specific viruses (either generic filters

or mail transfer agents (MTAs) bouncing an undeliverable message). However, it is not possible for automated software to ascertain the real sender with this degree of confidence in the case of most modern spoofing viruses. Indeed, even inspection by eye often fails to do this reliably. As a result, poorly configured antivirus services may inform the wrong person that their system is infected, and similarly mislead the intended recipient, leading to panic on the part of the wrongly blamed system's owner, to ill-feeling between the apparent sender and intended recipient, and maybe even to legal action (Harley 2003, Fact, fiction and managed anti-malware services).

Fortunately, antivirus companies have become much more aware of these problems, and are less likely to configure such behavior as a default. However, they are often reluctant to remove these configuration options altogether, so customers who do not understand the problem sometimes introduce inappropriate reconfigurations. Third-party managed e-mail antivirus providers may also reconfigure inappropriately, and may not have hooks to all the functionality of the core antivirus product.

A very high proportion of current infected e-mail traffic carries spoofing malware, so while it is responsible behavior to advise someone with an infected system of the fact when there is no doubt about the correct identification of the infected system, it is appropriate to do so only when the detected malware is known not to spoof headers. Many products and services cannot discriminate between viruses in this sense, even though they can identify the actual name of the virus correctly. The recipient should receive a message only if the removal of the viral code leaves a disinfected and useful object to be forwarded (as is the case with macro viruses), or if the forwarded message is a legitimate and intended communication from the sender. Most e-mail-borne viruses are not "infective" in the sense of attaching to a legitimate object. The message is initiated and controlled by the virus (or, more correctly, by the virus author who coded the message-generation mechanism), not the owner of the infected system, who is usually unaware of the presence and transmission of the malware. The "infected" file contains no legitimate code, so disinfection is effectively the same as deletion. There is, therefore, no reason to forward the message and no point (except advertising the product) in advising the intended recipient of the interception, certainly if the originating e-mail account cannot be accurately ascertained.

Unfortunately, many scanning services cannot distinguish cases in which it is not appropriate to send an alert or forward a message, or in which the malware is known to forge headers, and are not therefore able to modify their own behavior accordingly. In fact, some services cannot even be configured to stop alerts or forwarding at all. As a result, it can happen at times that the impact of secondary traffic from filtering and antivirus services vastly exceeds that of "real" mass-mailers and spam. (Harley 2004)

The Malware Author's Dilemma

The malware writer has a significant barrier to overcome if his program is to spread beyond his own development environment. Malicious programs are harmless unless they are executed. How does he get his code to run on someone

else's system? All malware exploits one or more vulnerabilities. These may consist of programming bugs and errors and other software vulnerabilities in a victim system, or of a lack of caution and skepticism in human victims, allowing them to be tricked into running unsafe programs, or in some cases, of a combination of the two.

"Self-launching" code exploits bugs such as buffer overflows, which can allow code to be run where it should not be. No action from the victim is necessary (Harley et al. 2001). The "Internet Worm" or "Morris Worm" of 1988 is as good an example as the far more recent MSBlaster or Code Red worms: possibly better, in that one of the vulnerabilities it exploited was in sendmail (Hruska 1992), whereas recent network worms have tended to exploit vulnerabilities in nonmail applications, such as IIS or SQL-Server. Mass mailers, however, have in some cases exploited vulnerabilities in mail applications, notably Outlook and Outlook Express (Microsoft 1999). There is a minor distinction to be drawn here between instances in which malware exploits miscoding and instances in which malware exploits (not necessarily intentionally) incautiously configured systems (as when office applications are set to allow macros to auto-execute, or mail clients are set to run attachments automatically).

"User-launched" code relies on persuading the victim to execute a malicious program, using social engineering in the general sense of psychological manipulation (Harley et al. 2001). Most e-mail-borne malware is user-launched or hybrid. Hybrid malware combines both the self-launching and user-launched approaches, thus maximizing the potential for spread. E-mail-borne malware is sometimes hybrid: it uses a bug such as those in some versions of Outlook that allow code to be run just by previewing a message, or the facility for auto-executing macros in Word or Excel, and thus requiring no intervention from the victim, but also hedges its bets by using what is often called social engineering to persuade victims to conspire in their own downfall by running an attachment. Such manipulation might persuade an unwary or unsophisticated computer user to open an executable file under the impression that it is a game or screensaver or even a data file. Most data files cannot carry executable code but Microsoft Office documents can, in the form of macros, and a Postscript file contains both programming instructions and data. This issue has long been recognized in antivirus circles, but has recently been revisited in more general security circles, notably on some specialist mailing lists. Not everyone realizes (for instance) that a screensaver (.SCR) is an executable program with the same format as an .EXE file, not a simple graphics file, and there are a multitude of well-documented ways in which an executable file might be "disguised" as a data file. For example, by using the "double filename extension" technique (examplefile.doc.scr) to hide the real file-type, or by presenting it as a self-extracting or self-decrypting archive file.

Trojan Horses

A Trojan horse (or simply a Trojan) tricks the victim into running its code by masquerading as something else (a desirable program). Most e-mail worms also do this, so they meet the definition of a Trojan, but they also replicate,

so they belong in the virus family. (In fact, there is an argument for claiming that viruses belong to the Trojan family, though to do so is not particularly helpful in practical terms, since it tends to increase confusion among nonexperts.)

Classic Trojans tend either to be destructive to data or to cause leakage of information (or both). They may include among other payloads:

- Damage to or loss of files and file systems
- Allowing access to the network via network shares
- Opening ports to allow traffic through the Internet gateway
- Sending passwords or data back to an unauthorized person
- Altering the configuration of a victim system
- Causing advertisements to pop up
- “Recruiting” compromised systems for use in botnets
- Track which Web sites victims visit, and which passwords they use.

Trojans’ main weakness as an e-mail-borne threat is that they are usually reliant on the quality of the social engineering in the accompanying message to gain a foothold into the system, and they cannot self-replicate even when they do gain a foothold (Harley 2002, Trojans). They include a wide variety of subclasses according to functionality, including among others:

- Destructive (Trojans that trash or overwrite files or file systems, most commonly)
- Backdoors (Trojans that attempt to open a connection to the victim computer from a remote system, for whatever purpose)
- Password stealers and keyloggers
- Porn dialers and other dialers (programs that use the modem on the infected machine to dial pornographic or other services, usually using premium rates and long-distance call charges).
- Distributed denial of service (DDoS) agents
- Rootkits (Trojanized versions of system files and other tools for concealing the presence of an intruder on a compromised system)
- Bots (in the sense of backdoor Trojans linked in a “botnet” that communicate and are controlled through Internet Relay Chat [IRC]).

Grimes (2001) also considers a class of program he calls parasites. Although these include such privacy-invasive nuisances as programs that “call home” and pass marketer-friendly data (often installed as part of a more-or-less legitimate and authorized program installation), there is also an argument for including objects with similar potential functionality such as adware, single-pixel GIFs, malicious cookies, and web bugs that can be accessed via e-mail incorporating active-content (PC Mag, 2006).

Bots and Botnets

The term *bot* is an abbreviated version of “robot.” In the context of software, it usually refers to some kind of agent

for remote control or information gathering (Overton 2005). In terms of e-mail threats, the term may be used to refer to “crawlers” that are used to seek out e-mail addresses (James 2005). However, bots (usually in the form of scripts) have long been used to automate processes on IRC (Canavan 2005). Such agents have long been used for legitimate and for malicious purposes. However, since 1999, when the PrettyPark worm used IRC as a channel for remote control and communication, and 2002, when SDbot and Agobot, among others, pioneered the emergence of binaries incorporating an IRC client (Harley and Bradley 2007), the impact of IRC bots on computing in general and messaging (and other security threats) in particular has grown alarmingly (Schiller & Binkley 2007). So-called zombie systems (PCs compromised by bot infestation), especially when combined into “botnets” under the control of a Bot Master (also known as a Zombie Master, Bot Herder, or Botmeister, among other terms), can be used for any number of malicious activities, from DDoS (distributed denial of service) attacks to spam, phishing, and malware dissemination, updating of malware, hosting of blind drop servers (for the collection and storing of phishing data), and so on. Similarly, bots can have a wide range of capabilities—vulnerability scanning; channel, UDP (User Datagram Protocol) and ping flooding; rootkit functionality, and password sniffing, for instance. Bots may be disseminated as e-mail (as attachments or as malicious hyperlinks), but are often distributed by other means. Nevertheless, they have a considerable secondary effect on messaging security.

Anti-Malware Solutions

The most effective answer to viruses is, of course, antivirus software, deployed not only at the desktop, but also on Web servers, file servers, and, most relevantly to this chapter, at the e-mail gateway. Unfortunately, this rather glib statement does not take into account all the realities of twenty-first century malware management. Old-fashioned viruses have declined significantly in volume and impact, while Trojans and blended threats constitute an increasing proportion of current malware problems (Braverman 2006). Although virus detection using both proactive and reactive techniques has attained an impressive technical level, there are limitations on the detection of nonviral threats that affect all antivirus products that extend their service to cover other forms of malware (nearly all of them, nowadays). These issues are considered further below. However, the virus threat has also changed, in that virus writers have moved away from hitting as many machines as possible and as quickly as possible with a single variant, to stealthier models of distribution (short spamming/seeding runs, frequent releases of repacked subvariants).

There are two main approaches to e-mail gateway-hosted virus management: generic and virus-specific. Generic virus management consists largely of discarding or quarantining objects that are capable of carrying or consisting entirely of a predetermined range of malicious code. In e-mail terms, this range usually consists of file attachments of file types often used by the writers of mass mailer viruses, including .PIF, .SCR, .VBS, .EXE, .BAT, .COM and

so on, though exactly which file types are blocked will depend partly on local usage. For instance, most sites do not block Microsoft Office documents, even though they are commonly associated with the passing of macro viruses, since legitimate business processes would suffer seriously from the blocking of legitimate documents. Table 1 classifies common attachment types by risk level (Harley 2004). Issues regarding the relative risks of common file types are also examined in considerably more detail in a Technical Note published by the UK's Centre for Protection of National Infrastructure (CPNI 2004).

Virus-specific software detects (obviously) known, specific viruses. A consideration of the precise mechanisms for such detection is beyond the scope of this chapter, but is based on a process of comparing code-bearing objects to a database of definitions, so that (in principle) a new definition (or search string) is required for each new virus or variant. In practice, the use of augmented detection by heuristic analysis and of generic drivers that are capable of catching some currently unknown variations and variants, sometimes lessens the impact of brand-new malware. However, the need still exists for updating antivirus software with the latest definitions (sometimes not altogether correctly referred to as signatures) as soon as they become available. Gateway systems and services should also be implemented with due regard to the need for configurability and appropriate alerting and forwarding mechanisms arising from the increase in header-spoofing mass mailers and allied problems, as described above and (at far greater length) by Harley (2003, Fact, fiction and managed anti-malware services). Modern antivirus programs often use advanced heuristic technology capable of detecting a very high percentage of new, unknown viruses and worms. However, it can be much harder to detect related forms of malware (especially nonreplicative malware) heuristically. Unfortunately, although the major vendors do exchange samples in order to maximize detection of known malware, changes in malware dissemination patterns mean that it is possible for some variants to remain undetected for a considerable length of time, sometimes months (James 2005).

The range and speed of spread of malicious code (e-mail-borne or not) also necessitates good systems and software patching practice at the server, desktop, and application levels and supplementary measures such as the blocking of vulnerable ports and services whenever possible and applicable; and it is no longer possible to consider virus management in complete isolation from other security technologies such as perimeter and desktop firewalls, intrusion-detection systems, and intrusion-prevention software. Policy and education remain a sometimes neglected but nonetheless essential component of a holistic security posture.

Although encryption is an essential adjunct to confidentiality in e-mail, it may also form part of the problem as regards the transfer of malicious code, and virus writers have made frequent use of the popular confusion between "encrypted" and "safe." The fact that a message or attachment is encrypted tells us nothing about whether it is infected. In most environments, encryption can be a barrier to effective gateway scanning, forcing the enterprise to rely on desktop scanning as a last-ditch defense,

notwithstanding the difficulties of maintaining desktop security products in large or fragmented corporate environments. Viruses such as Netsky and Bagle that present as encrypted .ZIP files indicate that even a comparatively trivial form of encryption can present challenges to conventional antivirus that have not yet been completely addressed. Indeed, generic filters that regulate the introduction of executable attachments can often be circumvented simply by zipping the viral program.

Public key infrastructure (PKI) can, if rigorously applied, have benefits in terms of control of mass mailers and some forms of spam, by making it harder for a message using deception and forgery as a means of delivery to survive an authentication mechanism. Applied purely as a means of managing e-mail abuse, however, it constitutes a somewhat expensive form of whitelisting (i.e., allowing only mail from approved addresses to reach the protected mailbox).

Anti-Trojan Software

Most antivirus software detects a reasonable proportion of all Trojans, joke programs, and similar nuisances, but antivirus vendors are not usually brave enough to claim that they can detect all known Trojans. There are a number of reasons for this, including:

- Difficulties in formal definition—the definition of a Trojan relies, in part, on the perception of the victim, a factor often not susceptible to automated code or text analysis.
- The fact that it is immeasurably easier to write trivial nonreplicative malware and introduce minor variants.
- The lack of a more-or-less universal Trojan-specific mechanism for sharing samples with trusted vendors and researchers comparable to those that exist for virus sample sharing.

Unfortunately, the same caveats tend to apply to the producers of Trojan-specific scanners, and rivalry between some Trojan specialists and the antivirus industry further complicates the issue. Similar problems are encountered in the detection of specific forms of Trojan such as bots, spyware, and adware.

SPAM AND RELATED E-MAIL ABUSE

The name *spam* is applied to a number of abuses involving the indiscriminate use of e-mail or newsgroup postings, though the use of the term as applied to newsgroup abuse is largely overlooked nowadays except by Usenet junkies.

E-mail spam includes the following:

- UCE—unsolicited commercial e-mail (junk mail): this term is applied to any unsolicited advertising. Most spam is disseminated with the intention of advertising a product or service, but other motivations may apply. Although the term can be and is applied to all unsolicited advertising, it is useful to discriminate between "honest" advertising (from more-or-less legitimate and

Table 1: Categorization of Attachment Types by Risk Level

Risk Level	Attachment Type
Very high risk	File types almost never exchanged legitimately by e-mail but are executable file types used by mail-borne malware: e.g. .PIF, .LNK, .BAT, .COM, .CMD, .SHS. These file types should, therefore, be blocked in all but the most exceptional circumstances. The .EXE file type is also heavily used by mass mailers and other malware, and is very frequently blocked by generic filters for this reason (and with good reason). However, it is included in the high-risk category rather than very-high-risk because it is possible and may be convenient for legitimate .EXE files to be exchanged, so blocking must remain a local decision. Filenames with double extensions, especially when one type is a nonexecutable and the last one(the one that matters) is executable: for instance. myfile.txt.pif. File types that do not match the filename extension, when the file type is more dangerous than the filename extension suggests Filenames with double or multiple extensions for which an attempt has been made to mask the presence of the real file type, for example by inserting several spaces between the penultimate extension and the real, final extension Files with a deceptive icon suggesting a nonexecutable file type Filenames that include the characters {}, suggesting an attempt to disguise an executable file type by using its CLSID (class ID extension)
Medium high risk	This category includes file types that are heavily used by mass mailers, but may also be exchanged legitimately (e.g., .EXE, .SCR, .VBS). It may be decided locally not to block these types for the following reasons: .EXE attachments may denote data rather than a “real” executable, but in the form of a program file—for example, self-decompressing archive files and self-decrypting files are often convenient because they do not oblige the recipient to own the archiving or encryption utility that generated them. It is hard to imagine that any organization still considers the attractions of exchanging fluffy screensavers to be worth the risk of allowing .SCR files, but again, the final decision must be local. Earlier mass mailers were very often VBScript files, and new .VBS mass mailers (and more current malware types) are still seen from time to time, but it can also happen that such scripts are used to install system patches, for example. Nonetheless, it is strongly recommended that if any of these file types must be allowed and exchanged by e-mail, that stringent precautions be taken to ensure that only trusted and trustworthy code is allowed through. Compressed archive files, especially the .ZIP file type characteristic of PKZip and WinZip, pose a significant risk, convenient as they are. Indeed, in the early years of the present decade, the use of encrypted .ZIPs and .RARs to transport mass mailers posed a major problem for mail administrators, though the problem has diminished as the mass mailer problem has diminished. Some generic filters are unable to check inside a compressed file for the presence of archived executables, though virus-specific software is almost always capable of scanning the contents of a .ZIP file (and a variety of other archive formats). However, virus-specific scanners are not able to scan the contents of encrypted archives in real time and have been forced to apply less satisfactory search criteria as more viruses have exploited this loophole. Also, multiply nested archives containing unusually large compressed files may constitute an effective denial of service attack on antivirus scanners and e-mail servers.
Medium risk	This class includes file types not frequently used by mass mailers, but capable of carrying executable/malicious code. Most file infectors, Trojans, etc. would be caught by the previous categories, but documents that can contain macros (especially Office documents) fall here. Note that exchange of some documents will often be seen as impacting too heavily on normal business practices to override the moderate increase in security (.DOC, .XLS), but others may be borderline high risk, such as those file types associated with Microsoft Access. People do not exchange full databases as often as they do more concise forms of data. Note, also, that the incidence of macro viruses has subsided. This trend may well be influenced by the fact that Microsoft applications no longer enable execution of unsigned macros by default.
Medium-low risk	This category includes executable files of types not currently associated with virus action, or only with extinct viruses, or zoo viruses (especially proof-of-concept viruses that exist only “to show it’s possible”)

(continued)

Table 1: (continued)

Risk Level	Attachment Type
Low risk	Nonexecutables. Technically, this should be “no risk.” However, it is impractical to prove automatically that a file contains no executable code.
Uncategorized	Files whose executability or infective status is presently unknown, or cannot be determined or assumed Files of unknown file type (or no explicit file type: Macintosh users are frequently penalized by generic checkers for the fact that Mac data files are often not given a filename extension) Encrypted files Archives that cannot be unpacked (fully or at all) for scanning Note that the last two categories can be said to include some file types in preceding categories: however, no presumptions are made in this case about filename extensions.

reputable organizations using more-or-less legitimate direct-marketing techniques) and advertising that includes a degree of deception not only in the content, but in the delivery mechanism. Reputable organizations generally conform to regulatory legislation. As well as being reasonably restrained in their claims regarding the products they are advertising, they obey (increasingly restrictive) laws.

- UBE—unsolicited bulk e-mail—is sent in bulk to many addresses. It may be and often is commercial, so is essentially a superset of UCE.
- NCE (nonresponsive commercial e-mail) is a term sometimes applied to spam sent by a company that fails to honor a user’s request to unsubscribe (James 2005).

The term is applied by many people to many divergent forms of unsolicited bulk e-mail. Most sources (especially antispam vendors!) suggest that well over 50 percent of all e-mail is now junk mail (some estimates suggest a much higher proportion, and almost all sources indicate continuing growth).

The term is still applied to bulk postings to Internet newsgroups (Usenet), but is now most commonly applied to unsolicited commercial and other bulk e-mail. It often involves advertising products or services, but may also be applied to many other types of unsolicited mail, including the following (some of these categories often overlap with other categories of e-mail abuse considered below, and may not always be considered “real” spam):

- Financial marketing messages that may or may not be genuine
- Product-oriented messages (general goods or services ranging from antivirus products to fake diplomas and qualifications to septic tanks and timeshare apartments)
- Illegal products or services (illicit drugs, pirated software etc.)
- Pornographic spam:
 - Hardcore
 - Softcore
 - Deviant

- Legal/illegal. The implications of legality may be far-reaching: for instance, processing of pedophilic content can, if not conducted in accordance with law enforcement guidelines, expose the recipient of such material to legal action.
- Offers of spamming software and services
- Health (diet-related, “improvement” of physical assets, medical supplies)
- “Spiritualist”/organized religion
- Other “soapboxing” from individuals with bees in their bonnets, religious, moral or otherwise.
- Fraud:
 - Pyramid and MLM (multilevel marketing) schemes
 - 419s (see below)
 - Credit card scams and other phishing attacks
- Leisure messages (prizes, online games, electronic greetings cards using wormlike replicative techniques to spread)
- Surveys
- Begging letters

Some find it useful to distinguish between “amateur” spam or unsolicited junk mail (commercial or otherwise) and “professional” or “hardcore” spam, which is not only unsolicited but includes a degree of deception, not only in its content, but as regards its origin.

I have proposed the following definition of “professional” spam elsewhere (Harley 2007) and will use it here, in the absence of a universally accepted standard: “Unsolicited and usually unwanted mail, often for advertising purposes, sometimes fraudulent, and generally including some degree of deception as to the source and purpose of the mail, such as forged From: fields, misleading Subject: fields, fake ‘opt-out’ mechanisms that don’t work or are used only to validate the address as a potential spam target, misleading pseudo-legal statements, and obfuscation of the originator of the spam mail.” Other commentators have made similar implicit assumptions about the nature of spam (Schwartz and Garfinkel 1998). Paul Vixie makes an excellent point—actually, several.

(see <http://tqmcube.com/contrib.php>). His definition has three dimensions to it:

1. The recipient's individual identity is irrelevant (the message is not personalized or significantly targeted).
2. The message is completely unsolicited.
3. From the recipient's point of view, the message gives a "disproportionate benefit to the sender."

Vixie's definition requires all three dimensions to be present.

Revenge spamming is a term sometimes applied to the implication of a disliked person (especially an antispammer) in spamming activities by using their site as a relay, fraudulently inserting their details into the mail headers, using their details in the body of the message, and so on. The victim of this sort of revenge spam subsequently becomes the victim of various sanctions applied by groups and individuals who are violently opposed to spamming. This form of abuse is closely allied to other forms of impersonation in which offensive or inappropriate mail is manipulated to make it look as if it came from someone else.

Some junk mail is clearly not expected to achieve anything other than to annoy or in some way distress the recipient, though in some instances it may be sent as a "probe" to test spamming software or to validate an address.

Malware writers also make use of spamming techniques to inject viruses, worms, and Trojan horses into the wild. Not only do they use deceptive headers and content to trick the recipient into opening the mail and running the malicious program attached, but they use spammer-like forgery of mail headers to disguise the true whereabouts and ownership of the infected system. They also use built-in SMTP servers to cover their tracks and maximize spread, in a manner highly reminiscent of some spamming tools, as well as using botnets.

Spam and Malware

A correlation has been noted between virus writing and spamming. (Hypponen 2003) Some mass mailers, bots, and other Trojans install software on infected systems that allow them to be used as open relays or open proxies by spammers, so that infected machines can be used to relay spam, increasing the potential spam-processing rate and the difficulty of tracing the real source of a spammed message. Since most corporate organizations nowadays maintain reasonable antivirus precautions—at least on the e-mail gateway, and hopefully on the desktop too—home computer systems are far more vulnerable to being exploited in this way. As long as most home computer users fail to install, configure, or maintain antivirus software correctly, it is probable that spammers will continue to make use of this approach. In fact, although home users do seem to be more aware of the risks and to be making attempts to protect their systems properly, it is increasingly difficult for antivirus companies to maintain the near-100 percent protection, not only from viruses and worms but from all other forms of malware, that antivirus users often expect.

Some malware is also known to install Web server processes on infected home (and other vulnerable) machines for the distribution and advertising of products and services that in themselves are often illegal. There have also been reports of infected systems being used to mount DoS attacks against antispam sites. Some malware forwards e-mail addresses and other information that may be used subsequently for spamming purposes.

However, mass-mailing malware also uses techniques analogous to those used by spambots to harvest target e-mail addresses not only from the victim's Windows address book, but often from other files and system areas such as Word documents, HTML files, web caches and so on. Mass mailers often use header forgery to spoof addresses and disguise the source of the infected mail and avoid early detection by gateway filters by using varying ("polymorphic") subject lines, message content, and made-up source addresses. The use by mass-mailer viruses of their own internal SMTP engines or known relays to self-disseminate also makes it harder to trace the source of infective mail or the footprint of the virus in the infected mail system. These spam-like techniques are symptomatic of increasing cross-pollination not only between virus/malware technology and spamming technology, but between malware authors, spammer communities, and phishing gangs (EEMA 2003; F-Secure 2005).

Chain Letters, Chain E-Mails, and Hoaxes

A chain letter is, in its broadest sense, any message that includes a request for the recipient to forward it. Terrestrial chain letters usually ask the recipient to forward a set number of copies, but chain e-mail usually asks the recipient to forward to "everyone they know" or "everyone in their address book" or "everyone who might use the Internet." The common denominator is that circulation increases in a geometric progression.

Chain letters are not necessarily hoaxes, but frequently contain some deceptive content, either through a deliberate attempt to mislead or because of a misunderstanding of the issue in question. Very frequently, fact is mixed in with fiction to add circumstantial credibility. It is possible for purely factual material to be forwarded in this way, of course, but in general, responsible (or for-fee!) distributors of quality information tend to use less intrusive forms of dissemination. The forwarding of messages by victims of pyramid scams is addressed in the later section on e-mail fraud, rather than as a form of chain letter, though there are certainly similarities between these two nuisances.

On their Hoaxbusters Web site, CIAC (2004) describe the chain letter as having a tripartite structure: hook, threat, and request. Although it is not always straightforward to separate these elements, they do seem to be common to most chain letters, electronic or otherwise.

The *hook* is there, like a riff in a popular song, to catch the recipient's interest, and consists of an eye-catching tag like "Free trainers!" or "Virus alert," and perhaps some expansion of the theme. It exploits some basic psychological issue like greed and self-interest, fear of technology and its consequences, or sympathy with the unfortunate (Harley 2000).

The *threat* pressures the recipient into passing on the message. Sometimes, the threat is simply that if the mark doesn't forward the mail, they will miss out on some personal advantage: for instance offers of free cell phones, sports gear, and so forth in return for meeting or exceeding a required number of forwardings. Less blatantly, a chain mail may exploit the desire to please or to earn brownie points or competitive advantage while doing something responsible and helpful, or the fear of being thought mean or uncharitable or unsympathetic (Harley and Gattiker 2002).

Direct threats may be used, somewhat in the fashion of older terrestrial chain mail that describe how recipients who did not forward met with misfortune or even death. More modern, less superstitious variations include threats to deluge the target's mailbox with spam or viruses.

It is more common for chain e-mail to use indirect threats that are not necessarily explicitly stated. For instance, behind virus hoaxes, there is the implicit threat of widespread damage and inconvenience personally and to all Internet users.

Some chain mail makes an overt emotional appeal such as that made by political petitions (such as those concerning the treatment of Afghan women under the Taliban, or opposing war with Iraq) or solicitations to forward e-mail to attract funding for cancer research. The threat is that if the mail is not forwarded, political injustice, cancer, or the suffering of an individual will continue unchecked, or a little boy's dying wish will not be granted, or child victims of a natural disaster like the 2004 tsunami will remain isolated from their parents or other family members. The common denominator is that all representatives of this class of nuisance ask the recipient to keep the chain going by forwarding e-mail, so that some undesirable outcome will be avoided.

The *request* expresses the "core function" of the chain letter: that is, to replicate by forwarding. The use of the term *replicate* is not accidental: chain letters, especially virus hoaxes, are sometimes considered to be "memetic viruses" (Gordon, Ford, and Wells 1997), or "viruses of the mind" (these commonly-used expressions and concepts largely originate in the writings and theories of biologist Richard Dawkins). Instead of the code used by computer viruses, which replicate by infection, chain letters rely on persuading the recipient to pass the message on to others. They often have a "payload" that results in the useless consumption of bandwidth through the replication of hoax e-mail, personal fear caused by scare stories with no basis in fact, and in some instances the erasure of legitimate software incorrectly identified as "viruses." However, they masquerade as an appeal to "help" others by disseminating "information," whereas cancer victim hoaxes ask you to generate money for medical research by forwarding identical messages, and others appeal to self-interest by offering money or free goods or services (clothes, cell phones, holidays, and so on).

Chain letters can be said to fall into three main classes:

- Pure fiction, intended to trick the victim into forwarding a chain letter and bolster the self-image of the originator by "proving" the stupidity of others. This class includes many virus hoaxes and other hoaxes related

to security—sometimes to other aspects of information security, but often to personal security such as vulnerability to robbery or personal attack. This latter class of hoax includes elements of the urban legend, especially those urban legends that have a gory or otherwise horrific element.

- Some hoaxes might be better described as semi-hoaxes, as they may be based on misunderstanding a real issue. Some virus hoaxes may fall into this class, but so do other hoaxes, such as widespread stories about highway speed cameras, telephone scams, and tsunami victims. However, a hoax with no basis in fact may nevertheless acquire a patina of circumstantial support as it passes from person to person. Such messages often originate from or are perpetuated by (for example) consultants, journalists, and others who are perceived, often inaccurately, as speaking authoritatively or from a position of exceptional knowledge. Rosenberger and others sometimes describe this as False Authority Syndrome, though this term is usually used in the context of virus hoaxes (Harley et al. 2001).
- More rarely, a security alert or other form of chain letter may be reasonably accurate in its content, but the form of transmission is inappropriate. Hoaxes and chain letters are not easy to manage using automatic software, though some sites do attempt to manage it using keyword filtering and Bayesian and other analytical techniques. However, these can lead to an unacceptably high false positive rate. In general, this is an area in which good policy and education works best, with good information resources as backup.

E-Mail Fraud

The following subclassifications are by no means all-inclusive, but do include some major current abuses.

Password Stealing

Attempts to gain password information, either by social engineering, the enclosure of some form of Trojan horse, or a combination of both, have long been associated with e-mail (Gordon and Chess 1998) and the use of particular ISPs—AOL users have been particularly victimized. However, this class of abuse is by no means ISP-specific, and can involve attempts to gain other types of information.

Phishing

This form of fraud, though it may be regarded in some instances as a special case of the preceding category, is also associated with malware distribution, and has become increasingly prevalent in recent years. In its most usual current form, it masquerades as a communication from a banking or other financial establishment (eBay and PayPal are very popular targets, but less obvious targets such as the IRS are increasingly exploited) asking the recipient to re-enter their banking details or other sensitive information into a form that appears to be generated at a legitimate Web site, or attaching (or persuading the recipient to download and run) malicious software such as keyloggers and bots. The scammer's intentions may include directly plundering the victim's bank or credit card account, but

may also be developed into more advanced forms of identity theft, such as taking out loans and mortgages in the victim's name.

Refinements of phishing technique include the exploitation of cross-site scripting vulnerabilities and setting up spoof Web sites. Spoofed Web sites and forms are often referenced by misleading and camouflaged Web links. Approaches involving the redirection of browser requests from legitimate to phish sites using DNS cache poisoning, corruption of the local "hosts" file, and so on, is sometimes referred to as "pharming."

Although some definitions emphasize the element of Web-site spoofing, there is a certain amount of crossover here between several types of e-mail abuse. At the moment, the efficacy of such frauds is often diluted by ineffective targeting, but it would be naïve to assume that fraudsters will not find ways of improving their credibility. Some reports (James 2005) suggest a much lower current response rate (between 0.01 percent and 0.1 percent), compared to that seen during the first half of the decade, but the return on investment (ROI) still provides massive incentive to phishing gangs to continue their activities. This type of identity fraud is extending into other business areas, and targets other types of data. Research by the Anti-Phishing Working Group (APWG 2006) and others (James 2005) suggests that the volume of dissemination of phishing scams has risen very quickly indeed, and that targeting and presentation of phishing mails have improved dramatically. The transmission of highly targeted phishing mails is sometimes termed "spear phishing."

Anti-phishing countermeasures include advanced content filtering, two- and three-factor mutual authentication between the end user and legitimate Web sites, and improving the quality of legitimate communications from phished organizations, to make them less easy to spoof. Some links to organizations working on improving consumer education and incident response are included in the "Further Reading" section at the end of this chapter.

Money Laundering and Mule Recruitment

Phishing is often associated with money-laundering activities (Rivner 2006), and e-mails intended to offer "jobs" described as "financial management" or "financial operations" usually turn out to be attempts to recruit "money mules" to sanitize funds stolen from phished accounts. Mules are needed to receive and forward money or goods acquired fraudulently from banks or credit card accounts. Like phishing mails, mule recruitment mails are often backed up by carefully constructed but fraudulent Web sites, and some mules do not realize that they are involved in money laundering until law enforcement agencies catch up with them. Unfortunately, this type of mail often manages to evade spam filters that are fairly effective at blocking phish mails, and this problem remains somewhat underreported and underestimated.

Pump and Dump Fraud

Pump and Dump (Penny Stocks, Pennystox, Hype and Dump) spam, though it relates to a very American form of trading in shares worth up to \$5 apiece, has been widely reported in the United Kingdom and elsewhere since about 2004. An increasing proportion of this spam has proved to

be intended to perpetuate stock fraud, to the benefit of organized crime (Wallener 2006; Harley and Lee 2007). These mails tend to use classic-spam-filter evasion techniques, such as image spam, with notable success. The basic spam is based on artificially inflating the price of low-priced stock the scammer holds by predicting a massive upward movement. As the victims rush to buy in, the stock value does indeed climb. When the scammer sells, however, and stops hyping the stock, the price plummets.

Pyramid Schemes and Multilevel Marketing

Pyramid schemes are based on the principle that the recipient of the e-mail sends money to a number of people, who send money to more people, who send money to more people ad infinitum. The idea is that eventually the recipient's name will rise to the top so that they too will receive money. They are generally associated with the selling of some token product or service. However, they make a profit only for the originator of the scam. Such scams often claim to be more-or-less legitimate multilevel marketing (MLM) operations. Ponzi schemes are another type of fake "investment" widely advertised by e-mail. Note that scam e-mails of this sort are often widely spammed, though they will usually need to point to a temporary but legitimate mailbox somewhere to which the money is directed. The mathematical model of some pyramid schemes resembles the model for the distribution of chain letters, especially those that specify the number of addresses to which you should forward them. This class of abuse is considered at some length by Barrett (1996).

Advance-Fee Fraud (419s)

Advance-fee frauds, better known as 419s or Nigerian scams (the name 419 derives from the section of the Nigerian Criminal Code dealing with fraud) are a long-standing type of scam that can be disseminated by fax, letter, etc. but is nowadays most often seen as e-mail. They constitute the largest proportion of current e-mail fraud, and work, broadly, as follows. The target receives an unsolicited communication containing a business proposal that often involves some form of money laundering or similar illegal operation, though if the proposal is obviously illegal, it often includes an attempt at moral justification and a comical plea to the recipient to act with honesty and integrity. Variations are endless, but may include:

- A request for help from a political refugee to get their family and their money out of a war-torn (usually African) country
- A request for help with the distribution of money for charitable purposes
- A request for assistance from a bank or other official with transferring money obtained more or less illicitly from the government
- A request to stand as "next of kin" for the purposes of claiming the estate of a dead foreigner who has died intestate
- Notification of a lottery win
- Phish-influenced offers of "jobs" that are likely to be linked to money laundering.

At some point, the victim is asked to pay advance fees of some sort (for example, for taxes, legal fees, or bribes or as evidence of good faith) or to give sensitive information about their own financial accounts. Some individuals have lost very large sums of money in this way.

These communications often but by no means always derive from Nigeria or another African state, but may originate or appear to originate from any part of the world. They often offer a URL pointing to a convincing but not necessarily relevant or genuine news item or other Web site, as circumstantial evidence.

These 419s are often regarded as indistinguishable from spam, and there are indeed many points of similarity. Like spammers, 419 perpetrators use target addresses harvested directly or indirectly from Web sites, newsgroups, mailing lists, and so on. However, they tend not to manipulate message headers so heavily, possibly because they need to maintain some sort of contact with the victim, though the contact point may be buried in the body of the message rather than the header, which may contain a forged address. They also make heavy use of “disposable” free e-mail accounts from Web mail providers: these are easily blocked when complaints are received, but are also quite difficult to trace, and less susceptible to automatic detection by filters that rely on header anomalies. They are, however, fairly susceptible to detection by filtering on keywords and phrases. Address information, text, and scam ideas are heavily recycled and exchanged, and some kinds of stereotyped “business English,” names and event information are frequently re-encountered by the dedicated 419-trapper.

Like spammers, 419 fraudsters generally use a scattergun approach. The messages are mailed to anyone whose address is harvested, irrespective of their likely interest, on the assumption that one or two potential victims will bite and make it worth the minimal initial investment required from the perpetrator.

However, there seem to be many “gangs,” individuals and countries operating this form of organized crime. It is strongly recommended that individuals, and the organizations they belong to, should *not* respond directly to such communications unless asked to by law-enforcement agencies.

There are a number of possibilities for dealing directly with 419s received. Individuals may be encouraged simply to delete them, of course, or report them to their local IT helpdesk or security administrator, who may be authorized to take immediate action to block, send alerts, and advise law enforcement, as well as finding it useful to monitor incoming fraudulent mail in order to keep records and to track trends in 419 technology and psychology. If a reporting mechanism exists, it is useful to include the whole message and full headers, but the From:, To:, and Subject: fields are the minimum likely to be needed for reactive blocking by domain or sender.

Possible direct action includes the following:

- Forward the e-mail to the abuse@[domain] account for the domains mentioned in the e-mail headers and in the message body, including full message headers.
- Forward to an appropriate law-enforcement agency: any local agency will give advice on how best to do this,

but some national resources are included in the Further Reading section at the end of this chapter. The 419 Coalition (2004) Web site includes contact addresses for several countries.

- In the event of a 419 with a likely Nigerian connection, file a complaint with the Nigerian Embassy or High Commission and with the Central Bank of Nigeria (info@cenbank.org).
- Where loss has occurred, a complaint can be filed with the Nigerian Economic and Financial Crimes Commission (EFCC) (info@efccnigeria.org). In many countries, it is also possible to report cases of contact and actual loss to national law-enforcement agencies, as well as to the local police. However, the sheer scale of this problem means that none of these parties will necessarily take action in every case, and if there has been no return communication with the fraudster, it's unlikely that there will be any direct response.

Threats and Extortion

There are as many possibilities for persuading or bullying an e-mail recipient into inappropriate and self-destructive behavior as human ingenuity and gullibility can accommodate. A common attack on individuals (especially those within corporate environments) is to send mail claiming to be able to take over their system and threatening to delete files or to unleash viruses or pornographic e-mail onto the individual's machine unless they pay a (sometimes comparatively small) sum (CNN 2003).

This form of attack is difficult to address by technical means, and is better addressed by corporate policy and education. It is noteworthy that the efficacy of this particular attack relies implicitly on organizational security being draconian and blame-oriented. Security is often improved by encouraging the end user to report incidents and breaches without fear of unjust retribution (Harley 1998).

Mail Bombing

This term is applied when an individual (or sometimes a site) is bombarded with e-mail messages, constituting a form of denial of service attack and invasion of privacy.

Subscription Bombing

This term is applied when rather than directly bombarding a target individual or site with e-mail, as in mail bombing, the target is subscribed to numerous mailing lists, especially high-volume lists. List-processing software nowadays includes a verification/confirmation mechanism by which an applicant subscriber is required to confirm their wish to subscribe. However, commercial mailing lists are not always so scrupulous.

E-Mail Abuse and Policy-Based Solutions

The following suggested policy outlines will not work for everyone in all respects, but highlight and to some extent address most of the core issues (Harley et al. 2001).

Acceptable Use of Facilities and Resources

Policies addressing the use and abuse of company resources may cover the use of e-mail, instant messaging, and access to the World Wide Web and other resources owned by the employer, specifying that they are intended for work purposes only, or for non-work purposes in moderation, according to local practice. Access should not be permitted to resources that customarily carry pornographic material, pirated software, and other illegitimate information and resources, such as malicious software (binaries or source code), including viruses, Trojan horses, backdoor/remote access tools, password-cracking tools, and hacking tools. Special considerations may apply as regards the use of Web-hosted mail services (and related or somewhat similar services such as Usenet, IRC, etc.)

All use of company facilities should be required to be in accordance with:

- All binding laws, including but not restricted to:
 - Data-protection legislation
 - Copyright legislation
 - Legislation concerned with unauthorized access or modification to systems or data
 - Trade-secrets legislation
 - Antidiscrimination legislation
 - Obscenity/pornography legislation, especially legislation relating to child pornography and pedophilia. Reporting and processing of problems relating to pedophilia is likely to require careful and unambiguous guidance, in order to conform with what is often complex and contradictory legislation.
- All internal policies
- Other policies and agreements by which the company is bound.

It might be considered appropriate here to proscribe the use of company resources for administration of private business ventures.

Acceptable Use of E-Mail

Staff using a company e-mail account, or other messaging facility, need to be aware that what they write will often be seen to represent the views and policies of the company. They should therefore be required to conform to appropriate standards of accuracy, courtesy, decency, and ethical behavior and to refrain from the dissemination of inappropriate mail content. Sending of bulk e-mail within the company or beyond should be consistent with internal policy, ethical practice, and legal and mandatory requirements.

Inappropriate behavior exposes the employee and the company to accusations of libel/defamation, harassment/discrimination, copyright infringement, invasion of privacy and so on. Employees are therefore required to act in accordance with the company's published policies as well as all applicable legislation and other binding agreements.

The company is probably not able or obliged to maintain constant surveillance of employees' use of its facilities,

especially where use is not specifically authorized or is misused, but employees should not assume an automatic right to privacy. Mail may be monitored or checked from time to time for reasons of maintaining network support, security, or other reasons, as well as for ensuring that it meets prescribed standards of conduct.

E-mail should not be used as if it were a secure communications channel for the transmission of sensitive information or messages. Use of encryption, however, should be in accordance with the company's policy and practice.

There should be no sharing of games, joke programs, screensavers etc. Any attachment is potentially hostile, irrespective of what it is claimed to be or the perceived trustworthiness of the source.

On no account should an end user be allowed to disable or reduce the functionality of security software without authorization.

End users should be expected to use the corporate standard antivirus package. Systems running unsupported security packages and other applications should be regarded as unprotected: this may have general support implications, as well as the obvious security implications.

Anti-Hoax and Chain Mail Policy

Chain e-mail is a drain on network resources, system resources, and support staff. Any mail that includes a request to forward widely and inappropriately should be regarded with suspicion and promptly reported, especially if it states or implies any sort of threat. Originating or forwarding mail that carries some sort of threat against recipients who do not forward it in turn should be regarded as a disciplinable offense. On no account should mail that warns of viruses, Trojan horses, and other security threats be forwarded without checking and authorization from the local IT unit, however apparently trustworthy or senior the source, unless they are specifically qualified and authorized to do so. Consider mandating the digital signing of such warnings or authorization, given how easy it is to forge headers. A number of recent spear phishes are manipulated so that they appear to be sent internally.

Some virus hoaxes may have been intended to discourage the forwarding of previously existing chain letters. This is *not* an acceptable reason for passing on a hoax or chain letter, and it may be worth addressing the issue specifically.

Passing on warnings about hoax warnings can be a difficult area. Some individuals and groups have recommended passing on information about hoaxes and chain letters back to other recipients of a hoax or chain letter, and in some extreme instances, to everyone in the recipient's address book.

- Passing on an anti-hoax message with instructions to the recipient to forward indiscriminately (or to a fixed number of people) is simply a chain letter, and should not be regarded as acceptable.
- Passing back an anti-hoax message to other hoax recipients may be justifiable if there are only a few of them

and if it is reasonable to assume that they will receive more benefit than annoyance from the information. Even then, the information should be accurate and subject to the approval of the appropriate manager.

- Not all hoaxes are security-related. Appeals to forward mail to raise money for a worthy cause (for example), even if not actually a hoax, may not be an appropriate use of company resources. End users should be educated to be skeptical, rather than believing that everything heard from Web sites, colleagues, newsgroups, or the media is true, or completely true.

Anti-Spam Policies

Employees should be strictly forbidden to use company resources for the dissemination of inappropriate mass e-mail for private or work-related purposes. Mailing lists specifically set up for dissemination of particular types of work-related information are an exception, if the type of information broadcast is appropriate to the list. However, spamming a mailing list should never be considered appropriate. Employees should be expected to react appropriately to spam and related nuisances. Advice should be available on when it is appropriate simply to trash messages and when it is required to report and (where appropriate) forwarding them to the appropriate quarter and following their advice on what further action to take, if any. Direct response to spam (including angry replies or following instructions to unsubscribe) can cause more damage than ignoring or simply deleting offending messages, and should be discouraged or controlled, subject to local policy. Spam that may have pedophilic content, for instance, may be subject to special handling considerations, depending on local legal frameworks.

“Spoofing,” “munging,” or forging mail headers in the headers of e-mail or news postings should be forbidden, whether as a means of disguising the source of mass e-mail (there is no legitimate business reason for doing this) or as a means of making it more difficult for spammers to harvest an address. Exceptions may be made for manipulating the address as in the interpolation of spaces or the substitution of AT and DOT for @ or the period character to make it harder for automatic harvesting software to recognize a valid address. (However, the effectiveness of such trivial manipulations against modern harvesting tools is likely to be disappointing.) Spoofing likely to ease the spoofer’s burden of junk mail at the expense of other legitimate users should be seriously discouraged. The use of anonymous e-mail should be considered specifically and according to local practice.

Advice should be available to end users on minimizing exposure to junk mail. Some research (Centre for Democracy and Technology 2003) suggests that the most common means for address harvesting is from the Web, so measures that might be explored include:

- Not publishing e-mail addresses unnecessarily on the Web, and obfuscating addresses where they *do* need to be published on Web sites. (This is a measure to avoid the automated harvesting of e-mail addresses by spammers, and should not be confused with the forging of e-mail headers, which is generally deprecated.)

- Restrictions on membership of and specific posts to newsgroups, Web forums and mailing-lists from work addresses except as required for work purposes.

It also makes sense at an administrative and technical level to consider mitigating the impact of direct harvesting attacks by mandating account names that may be less susceptible to automated guessing (dictionary) attacks than obvious formats like [firstname][surname-initial]@ or [firstname-initial][surname]@, and by specifying appropriate Mail Transfer Agent (MTA) configurations to counteract brute-force guessing attacks (e.g., by flagging traffic patterns that suggest such an attack preparatory to blocking the domain).

Codes of Conduct

All staff should be required to meet prescribed ethical standards, but particular attention should be paid to staff with special skill sets and corresponding privileges (technical management, MIS [Management Information Systems] personnel). It might be specified that all staff are expected to conform with the following strictures, which are staples of many codes of conduct used by IT professional peer organizations:

- Promote public health and safety
- Respect the legitimate rights of others—property rights, copyrights, intellectual property, and so on
- Comply with and maintain knowledge of standards, policies, and legislation
- Exert due care and diligence
- Refuse inducements
- Avoid disclosing confidential information
- Avoid conflicts of interest
- Conform to and maintain relevant professional standards in e-mail
- Advance public/customer knowledge
- Support fellow professionals
- Do not exceed their own expertise or authority
- Upgrade skills when opportunities exist
- Accept professional responsibility. Follow through and do not offload inappropriately or evade responsibility by blaming others.
- Access systems, data, resources only when authorized and when appropriate.

CONCLUSION

Even as the rest of us have taken to the Internet in general and e-mail in particular, the bad guys have quickly spotted the potential for exploitation, to the point at which legitimate traffic is increasingly swamped by e-mail abuse. These problems are accentuated by the essential insecurity of core messaging protocols, though the impact of these vulnerabilities can be mitigated by the application of encryption and authentication protocols such as TLS (Transport Layer Security), further supported by abuse-specific technologies such as antivirus (in its many forms)

and anti-spam technologies such as those described in this article. However, it can be assumed that spammers, virus writers, scammers, and other undesirables will continue to waste their energy and creativity on new ways to evade these technologies, at least as long as home users fail to protect themselves and businesses fail to supplement technical measures with education and policy.

GLOSSARY

419 (Nigerian Scam, Advance-Fee Fraud): A fraudulent communication, nowadays mostly e-mail, that attempts to persuade the target to take part in a (sometimes frankly illegal) scheme to transfer large sums of money to an account in the target's country, in return for a percentage of those funds. However, the victim is persuaded to part with sensitive financial information or sizable funds up front for taxes, bribes etc. and never sees any return. A common variation is to persuade the victim that they have won a lottery, but are required to pay local taxes before they receive their "winnings."

AUP (Acceptable Use Policy): Guidelines for users on what constitutes acceptable usage of a system, network services, etc.

Blacklisting: In spam management, the blocking or other special treatment of messages with particular attributes (e.g. originating from a known spam-friendly e-mail address or domain). A DNS blacklist (DNSBL) is a list of mail sources (usually IP addresses) associated with spam, and (ideally) continuously maintained by the addition and removal of addresses as appropriate, as a commercial or voluntary service. However, badly conceived and/or implemented blacklists can generate considerable false positive problems. (See also RBL).

Chain Letter: Originally a letter promising good luck if you pass it on to others or misfortune if you do not, thus breaking the chain. Hoax virus alerts are a special case of electronic chain mail: the recipient is urged to pass on the warning to everyone he or she knows.

Denial of Service (DoS) Attack: An attack that compromises the availability of system services and therefore data. DoS attacks in the e-mail context often consist of attempts to overwhelm a mail server or an individual's ability to handle mail by sheer volume of traffic, or to exceed an individual's quota of incoming e-mail (e.g. by mail-bombing or subscription bombing). When an attack is amplified by the use of many machines (as when linked in a botnet), the attack is referred to as a "distributed denial of service" (DDoS) attack.

Direct Harvest Attack (DHA): An attempt to harvest target e-mail addresses for spam or virus dissemination purposes, often by brute-force guessing of account names.

Ethics: Moral philosophy, dealing with human conduct and character. In the context of practical computer ethics, we are mostly concerned with "normative ethics," the establishment of a code of values based on accepted social norms, but applied specifically to the use of computers.

False Positive: Term used when software incorrectly diagnoses the presence of malicious software. In anti-spam

terms, it is usually applied to a message incorrectly identified as spam—such messages are sometimes referred to as "ham."

File Type: In the virus context, especially with reference to mass mailers, the important characteristic of a file type is whether it is executable—that is, whether it contains executable code, and that is the use of the term here. The file type may be indicated by the filename extension, and much generic filtering is based on checking that attribute, but a virus writer can change the extension to mislead the target. Some filters check file headers, which is generally more accurate but requires considerably more work and maintenance.

Hybrid Malware: Malware that can gain a foothold and execute on a target system both by exploiting a vulnerability in software and by using social engineering to track the system user, thus combining both the self-launching and user-launched approaches.

Malware: Malicious code (*malicious software*) such as viruses and Trojan horses.

Mass Mailer: A malicious program whose main or only infection mechanism is to mail itself out to e-mail addresses found on an infected system in the hope of persuading the recipient by social engineering into executing an attached copy of the mass mailer. (Some mass mailers may also use software vulnerabilities to force execution of embedded code without the intervention of the recipient.)

Message Headers: The part of an e-mail message that contains information about the identities of the sender and the intended recipient, where replies should be sent, and information about the route the message has taken to get from one party to the other. However, a very high proportion of e-mail abuse is enabled by the ease with which headers can be forged (either manually or automatically).

Ponzi Schemes: A fraudulent scheme by which the victim is persuaded to "invest" money. As the number of participants increases, the fraudster uses money sent by later investors to pay off early investors and build up numbers and confidence in the scheme, until he chooses to disappear with the money. The Internet offers virtually cost-less administration of such schemes.

POP: Post office protocol: allows a client machine to transfer e-mail from a server. Mail received via this protocol evades central anti-malware measures if applied only to an SMTP service, and unless the client machine has an up-to-date desktop antivirus program, it becomes vulnerable to mass mailers and other incoming e-mail abuse. Some organizations address this potential weakness by blocking port 110, thus disabling the service.

Pyramid Schemes: An allegedly profitable scheme by which one person sends money to a number of people who send money to a number of people ad infinitum. A common variation is to disguise this (generally illegal) scheme as a "legitimate" scheme to buy and sell mailing lists, software, t-shirts and so on.

Realtime Blackhole List (RBL): RBL is actually a service mark of MAPS LLC, but the term is often applied incorrectly to other DNS blacklists (DNSBLs).

Scam: An attempt to con money or services or information out of the victim. Scams always involve an element of deception, and may be distributed as a chain letter, among other means (including spam); 419s and phishing scams are particularly common at time of writing.

Self-Launching Malware: Malware, especially a worm, that exploits a vulnerability in software or operating systems rather than social engineering to gain a foothold and execute on a target system.

Signature: See "Virus Definition"

SMTP: Simple Mail Transfer Protocol. A core e-mail standard that is not, in itself, significantly secured against header forgery or breaches of confidentiality, and therefore open to a variety of forms of e-mail abuse.

Social Engineering: A term applied to a variety of attacks that rely on exploiting human weakness rather than technological loopholes. Often specifically applied to: (1) password stealing, and (2) manipulation of an e-mail recipient into running an attached malicious program, but has many other applications.

Spam: Unsolicited e-mail, especially commercial/junk e-mail. Also applied to the practice of posting large numbers of identical messages to multiple newsgroups. "Hardcore" or "professional" spam are terms sometimes applied to junk mail including a measure of deception (forged headers, misleading or even fraudulent content) and incorporates techniques intended to evade gateway filters and other anti-spam measures. The term derives, probably via a Monty Python sketch, from the canned meat marketed by Hormel who are understandably sensitive about the use of the name in the context of e-mail abuse.

UBE: Unsolicited bulk e-mail. The term is sometimes used synonymously with "spam."

UCE: Unsolicited commercial e-mail. Large subset of UBE with an overt commercial agenda. This term is also sometimes used synonymously with "spam."

User-Launched Malware: Malware that relies on social engineering to persuade a human victim to execute it.

Virus Definition: A scan string or algorithm used by a virus-specific scanner to recognize a known virus. Sometimes (but not altogether correctly) referred to as a signature, which in antivirus is usually taken to refer to matching a static string, a technique that has not been much used in that context for many years.

Virus-Specific Scanner: An antivirus scanner that checks an infectable object for indications that it is infected by a known virus, rather than for generic indications of possible infection. Essentially, it looks for matches to a virus definitions database. Sometimes referred to as a known virus scanner, or, less correctly, as a signature scanner.

Vulnerability: Condition of an asset in which a risk-reducing safeguard has not been applied, or is not fully effective in reducing risk. Sometimes used less formally to refer simply to a flaw, especially a programming error, which may require application of a patch.

Web Mail: A generic term applied to e-mail that, irrespective of the underlying mail transfer protocol, is accessed via a Web interface. Some mail services are accessible only by this means (Hotmail, Bigfoot etc.), but many ISPs include an additional Web interface facility as a courtesy to allow their customers to access their mail on systems other than their own PCs. From a security standpoint, a major corporate problem with Web mail stems from the fact that it is less susceptible to central filtering for viruses and other forms of abuse. However, many of the bigger providers apply their own antivirus and/or anti-spam measures.

Worm: A replicative, malicious program. The term is particularly applied to malware that spreads across networks and does not infect another program parasitically (as opposed to "true" viruses). The term is also often applied to mass mailers.

INTRODUCTION

The best way to come up with a definition of the term *virtual private network* (VPN) is to analyze each word separately. Having done that, Ferguson and Huston (1998) came up with the following definition:

A VPN is a communications environment in which access is controlled to permit peer connections only within a defined community of interest, and is constructed through some form of partitioning of a common underlying communications medium, where this underlying communications medium provides services to the network on a non-exclusive basis.

Ferguson and Huston also provided a simpler and less formal description of a VPN as a private network constructed within a public network infrastructure, such as the global Internet. Others define a VPN as a network that allows two or more private networks to be connected over a publicly accessed network. It is similar to wide area networks (WANs) or a securely encrypted tunnel. The chief feature of VPNs is that they use public networks like the Internet rather than using expensive, private leased lines while having similar security and encryption features as a private network (Obaidat and Boudriga 2007).

VPNs have evolved as a compromise for enterprises desiring the convenience and cost-effectiveness offered by shared networks, but requiring the strong security offered by private networks. Whereas closed WANs use isolation to ensure that data are secure, VPNs use a combination of encryption, authentication, access management and tunneling to provide access only to authorized parties and to protect data while in transit (Hunt and Rodgers 2003). To emulate a point-to-point link, data are encapsulated, or wrapped, with a header that provides routing information allowing it to traverse the shared or

public internetworks to reach its end point. To emulate a private link, the data being sent are encrypted for confidentiality. Packets that are intercepted on the shared or public network are indecipherable without the encryption keys (Arora, Vemuganti, and Allani 2001).

In order to enable the use of VPN functions, special software can be added on top of a general computing platform, such as a UNIX or Windows operating system. Alternatively, special hardware augmented with software can be used to provide VPN functions. Sometimes, VPN functions are added to a hardware-based network device such as a router or a firewall. In other cases, VPN functions are built from the ground up and routing and firewall capabilities are added. A corporation can either create and manage the VPN itself or purchase VPN services from a service provider (Strayer and Yuan 2001).

VPNs first appeared in 1984, when the service was offered to U.S. users by Sprint, with MCI and AT&T producing competing products soon after. In their initial form, VPNs were offered as a flexible, cost-effective approach to the problem of connecting large, dispersed groups of users. Private networks were the main alternative, and although equivalent functionality could be achieved via the public switched telephone network (PSTN), this was a limited solution because of the length of full national telephone numbers and the lack of in-dialing capabilities from the PSTN. Such a VPN acted as a PSTN emulation of a dedicated private network, using the resources of the PSTN in a time-sharing arrangement with other traffic (Hunt and Rodgers 2003).

Many forms of VPNs have existed in the technology's relatively short lifetime. The level of variety has resulted from the distinct domains of expertise of the companies developing and marketing VPN solutions. For example, hardware manufacturers may offer customer premise equipment-based solutions (i.e. devices installed at the company's headquarters and subdivisions), whereas an Internet service provider (ISP) would be more likely to offer a network-based solution (Hunt and Rodgers 2003).

The level of confusion and lack of interoperability between competing products led to the submission of a VPN framework to the Internet Engineering Task Force (IETF) in 1999, which defined VPNs as “the emulation of a private WAN facility using IP facilities.” A number of VPN implementations have been proposed to operate over a variety of underlying infrastructures and protocols, including asynchronous transfer mode (ATM), multiprotocol label switching (MPLS), Ethernet, IP, and heterogeneous backbones (Hunt and Rodgers 2003).

Traditional private networks facilitate connectivity among various network entities through a set of links comprised of dedicated circuits. These may be leased from public telecommunication carriers or may be privately installed wiring. The capacity of these links is available at all times, albeit fixed and inflexible. The traffic on these private networks belongs only to the enterprise or company deploying the network. Therefore, there is an assured level of performance associated with the network. Such assurances come with a price.

The drawbacks of this approach are:

Traditional private networks are not cheap to plan and deploy. The costs associated with dedicated links are especially high when they involve international locations [and security concerns are exacerbated due to the international transport of information]. The planning phase of such networks involves detailed estimates of the applications, their traffic patterns and their growth rates. Also, the planning periods are long because of the work involved in calculating these estimates. (Arora et al. 2001)

Further, dedicated links take time to install. It is not unusual that telecommunication carriers take sixty to ninety days to install and activate a dedicated link. Such a long waiting period adversely affects the company's ability to react to the quick changes in these areas (Arora et al. 2001).

Another trend is the mobility of today's workforce. Portable computing facilities such as laptops and palm-based devices have made it easy for people to work without being physically present in their offices. This also makes less investment into real estate (Arora et al. 2001).

To support the increase in home offices, companies need to provide a reliable information technology (IT) infrastructure so that employees can access a company's information from remote locations. This has resulted in large modem pools for employees to dial in. The cost keeps increasing because of the complexity of managing and maintaining the large modem pools. An additional cost with the mobile users is the long-distance calls or toll-free numbers paid for by the company. The costs are much higher if we consider international calling. For companies with a large mobile workforce, these expenses add up to significant numbers (Arora et al. 2001).

In addition, in the case of the private network, the company has to manage the network and all its associated elements, invest capital in network switching infrastructure, hire trained staff, and assume complete responsibility for the provisioning and ongoing maintenance of the network service. Such a dedicated use of transport services,

equipment, and staff is often difficult to justify for many small-to-medium-sized organizations, and while the functionality of a private network system is required, the expressed desire is to reduce the cost of the service through the use of shared transport services, equipment, and management (Ferguson and Huston 1998).

In this direction, VPNs promise to help organizations support sales over the Internet more economically, tying business partners and suppliers together, linking branch offices, and supporting telecommuter access to corporate network resources. A VPN can reduce costs by replacing multiple communication links and legacy equipment with a single connection and one piece of equipment for each location (Younglove 2000). In order to extend the reach of a company's intranet(s), a VPN over the Internet promises two benefits: cost efficiency and global reachability. However there are three major concerns about VPN technology: security, manageability, and performance (Günter 2001).

Security

In order for Virtual Private Networks to be private the transmitted data must be encrypted before entering the Internet, since the Internet is considered an untrusted network. Everybody can connect to the Internet and there is no guaranty that participants stick to any policy or rule. However, protecting the traveling data will not protect the information inside the Intranet from unauthorized access (Obaidat and Boudriga 2007; Günter 2001).

Manageability of VPNs

A company's telecommunication requirements and equipment evolve at a high speed. The VPN management must be able to cope with these changes while avoiding high expenses. VPNs are connected to many different entities that even by themselves are hard to manage and that constantly evolve. Such entities include the company's physical network (eventually featuring unregistered IP addresses), the company's security policy, the company's electronic services, and the company's ISPs (Günter 2001).

Performance of VPNs

Since ISPs deliver IP packets still on a “best effort” basis, the transport performance of a VPN over the Internet cannot be predicted, it is variable. Furthermore, security measures (encryption and authentication) can decrease transport performance significantly. This also points out two management problems: The clients must be enabled to (a) measure the performance, and (b) customize the VPN (e.g., the security options) in order to optimize it (Günter 2001).

A VPN solution consists of multiple, appropriately configured VPN devices that are placed in the appropriate locations within the network. As with any network, after all the VPN devices are installed and configured, the network should be continually monitored and managed (Strayer and Yuan 2001).

The most common VPN device is the VPN gateway, which acts as the gatekeeper for network traffic to and from protected resources. Tunnels are established from the VPN gateway to other appropriate VPN devices

serving as tunnel end points. A VPN gateway is usually located at the corporate network perimeter, and it acts on behalf of the protected network resources within the corporate intranet to negotiate and render security services. The gateway assembles the tunneling, authentication, access control, and data security functions into a single device. The details of how these functions are integrated within a VPN gateway are specific to a vendor's implementation. Sometimes these functions can be integrated into existing router or firewall products. Sometimes a VPN gateway can be a stand-alone device that performs pure VPN functions, without firewall or dynamic routing exchange capabilities (Strayer and Yuan 2001).

The data traffic coming from the public interfaces (inbound traffic) is thoroughly examined by the gateway according to the security policies. Usually, only the traffic from the established secure tunnels should be processed by the VPN gateway. If no secure tunnel is found, the traffic should be dropped immediately, unless its purpose is to negotiate and establish a secure tunnel. Depending on the implementation, an alert or alarm can be generated to notify the network management station (Strayer and Yuan 2001).

The data traffic coming from the private interfaces and exiting to the public interface (outbound traffic) is deemed secure a priori, even though many network attacks are generated within a corporate network. The outbound traffic is examined according to a set of policies on the gateway. If secure tunneling is required for the traffic, the VPN gateway first determines whether such a tunnel is already in place. If it is not, the gateway attempts to establish a new tunnel with the intended device—either another VPN gateway or simply some other device with secure tunneling capabilities. After the tunnel is established, the traffic is processed according to the tunnel rules and is sent into the tunnel. The traffic from the private interface can also be dropped if a policy cannot be found. Depending on how quickly a secure tunnel can be established, the VPN gateway may buffer the outbound packet before the secure tunnel is in place (Strayer and Yuan 2001).

The VPN client is software used for remote VPN access for a single computer or user. Unlike the VPN gateway, which is a specialized device and can protect multiple network resources at the same time, the VPN client software is usually installed on an individual computer and serves that computer only. Generally, VPN client software creates a secure path from the client computer to a designated VPN gateway. The secure tunnel enables the client computer to obtain IP connectivity to access the network resources protected by that particular VPN gateway.

VPN client software also must implement the same functions as VPN gateways—tunneling, authentication, access control, and data security—although these implementations may be simpler or have fewer options. For example, the VPN software usually implements only one of the tunneling protocols. Because the remote computer does not act on behalf of any other users or resources, the access control can also be less complex.

Unlike the VPN gateway, in which all of the gateway's hardware and software is geared toward the VPN functionality, VPN client software is usually just an application running on a general-purpose operating system on the remote

computer. Consequently, the client software should carefully consider its interactions with the operating system.

One of the important concerns regarding VPN client software is the simplicity of installation and operation. Because client software is expected to be deployed widely on end users' machines, it must be easily installed and easily operated by regular computer users who may not know much about the operating system, software compatibility, remote access, or VPNs. A VPN gateway, on the other hand, is usually deployed on the company's corporate network site and is managed by IT professionals.

VPN client software must work within the constraints of host computers' operating systems, whether the software is deeply integrated with the operating system or runs as an application. Because networking is a major function of today's computers, almost all modern operating systems have built-in networking functionality. However, few have strong support for VPN capabilities integrated into the operating system. As a result, separate VPN client software must be written for those operating systems that lack the VPN functionality. Furthermore, the same VPN client software may need to be ported to different operating systems, even for different release versions of the same operating system (Yuan 2002).

There are two fundamental architectures for implementing network-based VPNs: virtual routers (VRs) and piggybacking. The main difference between the two architectures resides in the model used to achieve VPN reachability and membership functions. In the VR model, each VR in the VPN domain is running an instance of routing protocol responsible for disseminating VPN reachability information between VRs. Therefore, VPN membership and VPN reachability are treated as separate functions, and separate mechanisms are used to implement these functions. VPN reachability is carried out by a per-VPN instance of routing, and a range of mechanisms is possible for determining membership. In the piggyback model the VPN network layer is terminated at the edge of the backbone, and a backbone routing protocol (i.e., extended border gateway protocol-4, BGP-4) is responsible for disseminating the VPN membership and reachability information between provider edge (PE) routers for all the VPNs configured on the PE (Ould-Brahim et al. 2003).

TYPES OF VPN SERVICES

A variety of VPN implementations and configurations exists to cater to a variety of needs (Metz 2003). Organizations may require their VPN to offer dial-up access or to allow third parties such as customers or suppliers to access specific components of their VPN (Hunt and Rodgers 2003). VPNs can be classified into three broad categories: intranet, extranet, and remote-access VPNs. VPNs can be classified into three broad categories, which are illustrated in Figure 1: intranet, extranet and remote-access VPNs.

Intranet VPNs

An intranet VPN connects a number of local area networks (intranets) located in multiple geographic areas over the shared network infrastructure (Venkateswaran

2001). Typically, this service is used to connect multiple geographic locations of a single company (Arora et al. 2001). An intranet VPN enables the sharing of information and resources among dispersed employees. For example, branch offices can access the network at the head office, typically including key resources such as product or customer databases. Intranet access is strictly limited to these networks, and connections are authenticated. Differing levels of access may be allocated to different sites on the intranet, depending on their purpose (Hunt and Rodgers 2003). Since an Intranet VPN is formed by connecting two or more trusted sites (corporate LANs), which will certainly be protected by firewalls, most security concerns are alleviated.

Extranet VPNs

An extranet VPN extends limited access to corporate computing resources to business partners, such as customers or suppliers, enabling access to shared information (Wright 2000). Such users are restricted to specific areas of the intranet, usually denoted as the demilitarized zone (DMZ). It is the responsibility of the firewall and authentication and access-management facilities to distinguish between company employees and other users, and differentiate their access privileges accordingly; employee connections should be directed to the company intranet, whereas recognized third-party connections should be directed to the DMZ (Hunt and Rodgers 2003). An extranet VPN helps provide connectivity to new external suppliers and customers within a short time. In addition, an

extranet VPN supports a number of important e-commerce initiatives, providing opportunities for significant cost savings and efficiency gains.

A number of possible extranet configurations exist, which vary in their level of security and access. The most common examples, in order from most to least secure, are listed below (Hunt and Rodgers 2003).

1. *Private extranet.* Access to a private Extranet is strictly for members only, with no use made of shared networks. Such a configuration cannot be considered a VPN, as it is physically private.
2. *Hybrid extranet.* A hybrid extranet is equivalent in operation to a private extranet, except that it uses one or more shared network to provide connectivity. Membership is restricted, and access to private resources is limited to relevant resources only.
3. *Extranet service provider.* This configuration is offered by an ISP, which builds extranet services based on its backbone network. This is a type of provider-provisioned VPN.
4. *Public extranet.* A public extranet provides data that are globally accessible. An example is a company that provides a public Web site and possibly a public FTP (file transfer protocol) site that Web users are free to access. Such facilities are normally distinct and separate from private file servers, so that public servers cannot be used as staging points for compromising the private component of the extranet.

Figure 1: Types of VPN services

Remote-Access VPNs

A remote-access VPN connects telecommuters and mobile users to corporate networks. An ideal VPN enables the remote user to work as if he or she were at a workstation in the office. Deployment of a remote-access VPN can result in considerable cost savings, eliminating the need for the company to manage large modem pools, and replacing the need for toll calls to these modems with calls to local ISP accounts. By taking advantage of a high-speed access infrastructure such as DSL (digital subscriber line), cable modem, or ISDN (integrated services digital network), some of the performance limitations typically associated with remote access can be diminished (Hunt and Rodgers 2003). In addition, wireless networks enable computers to achieve network connectivity with a reasonable amount of bandwidth without a physical connection (Ribeiro, Silva, and Zuquete 2004).

The deployment of remote-access VPNs also gives rise to several security concerns. Precautions must be taken to ensure that the corporate network is not compromised by an insecure remote user. The enforcement of company security policies on remote users is a necessary step in this direction, especially regarding virus protection. It must be noted that the increased flexibility of wireless networks raises additional security issues. On one hand, given the ubiquitous nature of the communication channel, clients of the infrastructure must be authenticated, in order to avoid unauthorized users gaining access to network resources. On the other hand, since any wireless device may listen on the communication channel, data encryption must be enforced if some level of data protection and confidentiality is desired. The security concerns relating to VPNs are discussed in more detail in the following sections.

Table 1 summarizes the characteristics of the types of VPNs that were discussed above.

TUNNELING

Tunneling is defined as the encapsulation of a certain data packet (the original or inner packet) into another data packet (the encapsulating, or outer packet) so that the inner packet is opaque to the network over which the outer packet is routed (Strayer and Yuan 2001).

The need for tunneling arises when it is not appropriate for the inner packet to travel directly across the network for various reasons. For example, tunneling can be used to transport multiple protocols over a network based on some other protocol, or it can be used to hide source and destination addresses of the original packet. When tunneling is used for security services, an unsecured packet is put into a secure, usually encrypted, packet (Strayer and Yuan 2001).

Tunneling allows network traffic from many sources to travel via separate channels across the same infrastructure, and it enables network protocols to traverse incompatible infrastructures. Tunneling also allows traffic from many sources to be differentiated, so that it can be directed to specific destinations and receive specific levels of service (Wright 2000). Two components can uniquely determine a network tunnel: the end points of the tunnel and the encapsulation protocol used to transport the original data packet within the tunnel (Strayer and Yuan 2001).

Tunneling is the most important mechanism used by VPNs. The idea behind this concept is that a part of the route between the originator and the target of the packet is determined independently of the destination IP address. The importance of tunneling in the context of access VPNs in broadband access networks is twofold (Cohen 2003). First, the destination address field of a packet sent in an access VPN may indicate a non-globally-unique IP address of a corporate internal server. Such an address must not be exposed to the Internet routers because these routers do not know how to route such packets. Second, very often a packet sent by a user of an access VPN should be forwarded first to the ISP of this user, and only then from the ISP toward the corporate network. In such a case, the first leg of the routing between the host and the ISP cannot be performed based on the destination IP address of the packet, even if this address is globally unique (Cohen 2003).

The devices at one or both ends of a tunnel could be network address translation (NAT) devices. NAT is another important mechanism used by VPNs. The need for IP address translation arises when a network's internal IP addresses cannot be used outside the network either because they are invalid for use outside or because the internal addressing must be kept private from the external network. Address translation allows hosts in a private

Table 1: Types of VPN Services

	Intranet VPN	Extranet VPN	Remote-Access VPN
Typical scenario	Multiple geographical locations of a single company	Two or more companies have networked access to a limited amount of each other's corporate data	Mobile users connecting to corporate networks
Typical Users	Employees working in branch offices	Customers, suppliers	Employees working at home or on the road
Security Concerns	Minor	Medium	Major
Implementation	Two or more connected LANs	A company LAN connected to another company's DMZ	Remote users dial up to the corporate network

network to transparently communicate with destinations on an external network and vice versa. NAT is a method by which IP addresses are mapped from one address realm (i.e., network domain) to another, providing transparent routing to end hosts (Srisuresh and Holdrege 1999).

Two main types of tunneling techniques are used by VPNs (Hunt and Rodgers 2003):

- *End-to-end tunneling (also known as “transport model” tunneling)*. The VPN devices at each end of the connection are responsible for tunnel creation and encryption of the data transferred between the two sites, so the tunnel may extend through edge devices such as firewalls to the computers sending and receiving the traffic. Secure sockets layer/transaction layer security (SSL/TLS) is an example of a protocol that uses end-to-end tunneling. This solution is extremely secure, because the data never appear on the network in clear-text form. However, performing encryption at the end hosts increases the complexity of the process of enforcing security policies. The network gateways, which would normally be responsible for enforcing security policy, are used only for forwarding the packets to their destination in this scenario, and as such, they possess no knowledge of the content or purpose of the traffic. This is particularly problematic for filtering programs installed at the gateway.
- *Node-to-node tunneling*. Node-to-node tunnel creation and termination occurs at the gateway devices comprising the edge of the networks, which are typically firewalls. In this model, transport within the LANs remains unchanged, as it is assumed that internal traffic is inaccessible from outside the LAN. Once traffic reaches the gateway, it is encrypted and sent via a dynamically established tunnel to the equivalent device on the receiving LAN, where the data are decrypted to recover their original format, and transmitted over the LAN to the intended recipient. This has an additional security advantage, in that an attacker operating a network analyzer at some point on the network between the two tunnel servers would see IP packets with the source and destination addresses corresponding to those two servers—the true source and destinations are hidden in the encrypted payload of these packets. Since this information is hidden, the would-be attacker does not gain any indication as to which traffic is heading to or from a particular machine, and so will not know which traffic is worth attempting to decrypt. This also eliminates the need for NAT to convert between public and private address spaces, and moves the responsibility for

performing encryption to a central server, so intensive encryption work does not need to be performed by workstations. This is especially important when using costly encryption algorithms such as 3-DES (triple data encryption standard), which requires hardware encryption support in order to operate without limiting the effective bandwidth.

There are two main drawbacks associated with node-to-node tunneling (Hunt and Rodgers 2003):

1. *Poor scalability*. The number of tunnels required for a VPN increases geometrically as the number of VPN nodes increases, and that has serious performance ramifications for large VPNs.
2. *Suboptimal routing*. Since tunnels represent only the end points and not the path taken to reach the other end of the tunnel, the paths taken across the shared network may not be optimal, which may cause performance problems.

One can also distinguish two different tunneling modes—that is, “voluntary” and “compulsory” tunneling. *Voluntary tunneling* is a method in which the tunnel is created at the request of the user for a specific purpose, while *compulsory tunneling* is when the tunnel is created without any action from the user, and without allowing the user any choice in the matter (Ferguson and Huston 1998). The concepts of compulsory and voluntary tunneling are illustrated in Figures 2 and 3, respectively. In both figures, a host is attempting to connect to a corporate network using a dial-up connection to a network access server.

There are a number of desirable characteristics for a VPN tunneling mechanism. These include (Gleeson et al. 2000; Rosenbaum, Lau, and Jha 2003):

- *Multiplexing*. There are cases in which multiple VPN tunnels may be needed between the same two IP end points. This may be needed, for instance, in cases in which the VPNs are network-based, and each end point supports multiple customers. Traffic for different customers travels over separate tunnels between the same two physical devices. A multiplexing field is needed to distinguish which packets belong to which tunnel. Sharing a tunnel in this manner may also reduce the latency and processing burden of tunnel setup.
- *Signaling protocol*. There is some configuration information that must be known by an end point in advance of the tunnel establishment, such as the IP address of

Figure 2: Compulsory tunneling scenario

Figure 3: Voluntary tunneling scenario

the remote end point, and any relevant tunnel attributes required, such as the level of security needed. Once this information is available, the actual tunnel establishment can be completed in one of two ways—via a management operation or via a signaling protocol that allows tunnels to be established dynamically. Using a signaling protocol can significantly reduce the management burden, however, and as such, is essential in many deployment scenarios. It reduces the number of configurations needed, and also reduces the management coordination needed if a VPN spans multiple administrative domains.

- **Data security.** A VPN tunneling protocol must support mechanisms to allow for whatever level of security may be desired by customers, including authentication and/or encryption of various strengths. If some form of signaling mechanism is used by one VPN end point to dynamically establish a tunnel with another end point, then there is a requirement to be able to authenticate the party attempting the tunnel establishment.
- **Multiprotocol transport.** In many applications of VPNs, the VPN may carry opaque, multiprotocol traffic. As such, the tunneling protocol used must also support multiprotocol transport.
- **Frame sequencing.** Sequencing may be required for the efficient operation of particular end-to-end protocols or applications. In order to implement frame sequencing, the tunneling mechanism must support a sequencing field.
- **Tunnel maintenance.** The VPN end points must monitor the operation of the VPN tunnels to ensure that connectivity has not been lost, and to take appropriate action, such as route recalculation, if there has been a failure.
- **Support for large maximum transmission units (MTUs).** If the tunnel's MTU is larger than the MTU of one or more individual hops along the path between tunnel end points, some form of frame fragmentation will be required within the tunnel. If the frame to be transferred is mapped into one IP datagram, normal IP fragmentation will occur when the IP datagram reaches a hop with an MTU smaller than the IP tunnel's MTU. This can have undesirable performance implications at the router performing such midtunnel fragmentation. An alternative approach is for the tunneling protocol itself to incorporate a segmentation and reassembly capability that operates at the tunnel level. This avoids IP level fragmentation within the tunnel itself.

- **Minimization of tunnel overhead.** Minimizing the overhead of the tunneling mechanism is beneficial, particularly for the transport of jitter and latency sensitive traffic such as packetized voice and video. On the other hand, the security mechanisms that are applied impose their own overhead; hence, the objective should be to minimize overhead over and above that needed for security, and to not burden those tunnels in which security is not mandatory with unnecessary overhead.
- **Quality of service (QoS)/traffic management.** Customers are expected to require that VPNs yield similar behavior to physical leased lines or dedicated connections with respect to QoS parameters such as loss rates, jitter, latency, and bandwidth guarantees. How such guarantees could be delivered will, in general, be a function of the traffic management characteristics of the VPN nodes themselves, and the access and backbone networks across which they are connected.

Three major tunneling protocol suites have been developed for building VPNs: point-to-point tunneling protocol (PPTP), layer two tunneling protocol (L2TP), and Internet protocol security (IPSec). These protocols are discussed later in this chapter.

SECURITY CONCERNS

Security concerns that arise when transmitting data over shared networks can be divided into the following categories (Hunt and Rodgers 2003):

1. **Privacy.** Can unauthorized parties gain access to private VPN traffic? Privacy can be achieved through the use of encryption.
2. **Integrity.** Can VPN traffic be altered without detection? Integrity is generally achieved through the use of checksums.
3. **Authentication.** Can I be certain that the sender or recipient is really who they claim to be? Authentication is usually performed by confirming that the other party has knowledge of or is in possession of some shared secret or unique key.
4. **Nonrepudiation.** Can the sender or receiver later deny their involvement in a transaction? Nonrepudiation, also known as data origin verification, is often achieved through the use of digital signatures. When nonrepudiation measures are in place, the recipient cannot deny

having received the transaction, nor can the sender deny having sent it (Hunt and Rodgers 2003).

There are two main trust models applicable to the use of a shared backbone network (Hunt and Rodgers 2003):

1. *Untrusted service provider.* In this scenario, the customer does not trust their service provider to provide security for VPN traffic, preferring instead to use devices that implement firewall functionality, passing data between these devices using secure tunnels. The role of the service provider in this scenario is solely that of a connectivity provider.
2. *Trusted service provider.* In this scenario, the customer trusts the service provider to provide a secure, managed VPN service. Specifically, the customer trusts that VPN packets will not be misdirected, that their contents will not be inspected or modified while in transit, and that they will not be subjected to traffic analysis by unauthorized parties.

Cryptography

Cryptographic algorithms are essential for achieving secure communications over shared networks, as a would-be attacker may obtain and store all the packets of a data stream belonging to a specific communication as it traverses the shared network. There are a number of encryption algorithms available, many of which support varying levels of security. The algorithms most commonly applied to VPNs are the data encryption standard (DES) and triple DES (3-DES). DES has been the de facto standard in data communications for a number of years, but the ever-increasing processing capacity of computers has reached the point at which only the larger key lengths supported by DES should be considered secure (Hunt and Rodgers 2003).

Increased security generally comes at the cost of reduced performance, so a balance between efficiency and security must be achieved when applying encryption; the expected time for an attacker to complete a brute-force cipher attack should exceed the length of time for which the data remain valuable. If this requirement cannot be met effectively, alternative options such as dynamic key renegotiation within a given data stream may improve security without necessarily having a significant impact on performance. Such a process forces an attacker to decrypt small blocks of data at a time, dramatically increasing the difficulty of retrieving the clear-text for the entire message (Hunt and Rodgers 2003).

Integrity Checksums

A checksum is a series of bits of fixed length, whose value is derived from a given block of data. Checksums are often appended to a block of data prior to transmission, so that the receiver can verify that the data were received in the exact condition in which they were sent (Hunt and Rodgers 2003). Simple checksums are merely a count of the number of bits in a transmission unit, which is insufficient for security purposes, as it provides no means of verifying the integrity of the received data, only that it

is of the correct size. Hash functions introduce a greater computational overhead than a simple tally, but allow verification that the transmission was received successfully, free from transmission errors or deliberate tampering en route. The hash value, also known as a message digest, concisely represents the longer message or document from which it was derived. A message digest acts as a form of “digital fingerprint” of the original document, and can be made public without revealing the contents of the corresponding document (Hunt and Rodgers 2003).

Authentication

Authentication of VPN users is generally performed by confirming the knowledge of some shared secret. Passwords are the most user-friendly option, although the process may incorporate tokens or smart cards if enhanced security is required. Digital certificates are a reliable way of providing strong authentication for large groups of users (Hunt and Rodgers 2003). Because passwords can be cracked or sniffed, authentication methods that use static password authentication should be considered insecure, particularly if the authentication session is not encrypted (Hunt and Rodgers 2003).

There are three distinct factors for authentication (Hunt and Rodgers 2003):

1. *What do you know?* This fact should be known only by the user and the verifier, and should be infeasible to guess or derive. A common application of this factor in VPNs is an alphanumeric password, which is verified by an authentication server using an authentication protocol.
2. *What do you have?* In VPNs, this factor will typically be some form of identification card, smart card, or token. Such items should be unique and difficult to forge.
3. *What you are.* This refers to some unique attribute of the user, such as a fingerprint or voiceprint, that is impractical to forge or imitate. Such authentication methods are rarely used in VPNs at this time.

Access Management

It is not always sufficient merely to authenticate a user; too often it is assumed that once a user has been granted access, he or she should have widespread access to almost all resources on the VPN (Hunt and Rodgers 2003). This is a potentially dangerous assumption, since insiders can pose as great a threat to the security of an organization as outsiders; they may have various advantages beyond privileges and access rights, such as a superior knowledge of system vulnerabilities and the whereabouts of sensitive information. Despite the risks involved, the problem of protecting a VPN and its resources from insiders is often assigned a relatively low priority, if it is not ignored altogether (Hunt and Rodgers 2003).

This is where access management techniques can be a valuable tool. Using access management tools, such as Kerberos (a hardware and/or software implementation), an enterprise can ensure that insiders are granted access only to resources for which they have been explicitly assigned access rights. Usually, the process of managing and

Table 2: VPN Security Concerns

Security Concern	Privacy	Integrity	Authentication	Nonrepudiation
Relevant Question	Can unauthorized parties gain access to private VPN traffic?	Can VPN traffic be altered without detection?	Can I be certain that the sender or recipient is really who they claim to be?	Can the sender or receiver later deny their involvement in a transaction?
Solution	Encryption	Checksums	Possession of secret key	Digital signatures

restricting access to VPN resources involves maintaining an access control list (ACL) for each of the resources for which use is restricted to specific users or groups of users. When a user attempts to access a given resource, the access management tool consults the ACL for that resource, and will subsequently grant access only if that user is represented in the list (Hunt and Rodgers 2003).

Security concerns relating to VPNs are summarized in Table 2.

VPN IMPLEMENTATIONS

One can distinguish between two fundamental VPN models, namely the peer and the overlay model. In the peer model, the network-layer forwarding path computation is implemented on a hop-by-hop basis, in which each node in the intermediate data transit path is a peer with a next-hop node. In contrast, in the overlay model, the network-layer forwarding path computation is not implemented on a hop-by-hop basis, but rather, the intermediate-link-layer network is used as a “cut-through” to another edge node on the other side of a large cloud (Ferguson and Huston 1998). The overlay model introduces some serious scaling concerns in cases in which large numbers of egress peers are required. This is because the number of adjacencies increases in direct relationship with the number of peers; thus, the amount of computational and performance overhead required to maintain routing state, adjacency information, and other detailed packet forwarding and routing information for each peer becomes a liability in very large networks. If all egress nodes in a cut-through network become peers, in an effort to make all egress nodes one “layer 3” hop away from one another, this limits the scalability of the VPN overlay model quite remarkably (Ferguson and Huston 1998).

A number of approaches may be taken to the problem of providing VPN links and services. In particular, a VPN may be implemented and secured at a number of layers of the TCP/IP protocol stack (Knight and Lewis, 2004). The most significant of the currently available approaches are described below.

Network-layer VPNs (Hunt and Rodgers 2003): Network layer VPNs, based primarily on IP, are implemented using network-layer encryption, and possibly tunneling. Packets entering the shared network are appended with an additional IP header containing a destination address, which corresponds to the other end of the tunnel. When this node receives the packet, the header is removed and the original packet, which is addressed to some location

within the given network, is recovered. Because of this encapsulation, the original packets could be based on any network-layer protocol without affecting their transport across the shared network.

Data-link-layer VPNs (Hunt and Rodgers 2003): Data-link-layer VPNs use a shared backbone network based on a switched-link-layer technology such as frame relay (FR) or ATM. Links between VPN nodes are implemented as virtual circuits, which are inexpensive, flexible, and can offer some level of ensured performance. Link-layer VPNs are most appropriate for providing intranet services; dial-up access is not well supported, as most ISPs provide connectivity using IP. Most of the cost savings associated with VPNs are the result of the use of ISPs. Therefore, IP-based network-layer VPNs are more attractive than link-layer VPNs if dial-up access is required. Virtual-circuit based VPNs face scalability issues similar to those of node-to-node tunneled VPNs, so a full-mesh architecture may not be possible. Alternatives such as partial meshes or hub-and-spoke configurations address this limitation to some extent, but these solutions may produce suboptimal behavior, especially for routing, introducing performance concerns.

Application-layer VPNs (Hunt and Rodgers 2003): Application-layer VPNs are implemented in software, whereby workstations and servers are required to perform tasks such as encryption, rather than assigning these tasks to specialized hardware. As a result, software VPNs are inexpensive to implement but can have a significant impact on performance, limiting network throughput and producing high CPU usage, particularly over high-bandwidth connections.

Non-IP VPNs (Ferguson and Huston 1998): It is widely recognized that multiprotocol networks may also have requirements for VPNs. The most pervasive method of constructing VPNs in multiprotocol networks is to rely on application-layer encryption, and as such, are generally vendor proprietary, although some would contend that one of the most pervasive examples of this approach was the mainstay of the emergent Internet in the 1970s and 1980s—that of the UUCP (UNIX-to-UNIX copy protocol) network, which was (and remains) an open technology.

Hardware Components

A number of hardware devices are required to implement the various types of VPNs discussed above. Many of these devices are common to standard networks, but some have additional burdens and responsibilities placed

on them when applied to VPNs and their specific requirements. The main hardware devices used by VPNs, and the implications of any additional processing that they must perform are discussed below (Hunt and Rodgers 2003).

Firewalls: VPNs must be protected from other users of the backbone network. This is typically achieved using a firewall, which provides critical services such as tunneling, cryptography, and route and content filtering (Hunt and Rodgers 2003).

Routers: Adding VPN functionality to existing routers can have an unacceptable performance impact, particularly at network stress points. Specifically, multiprotocol label switching (MPLS) VPNs address this problem by making only the perimeter (PE) routers VPN-aware, so the core routers need not maintain the multiple routing tables that introduce so much overhead on PE routers (Hunt and Rodgers 2003).

Switches: Some switches offer facilities for increased separation of traffic by allowing a physical network to be partitioned into a number of virtual LANs (V-LANs). On a normal switch, all ports are part of the same network, whereas a V-LAN switch can treat different ports as parts of different networks if desired (Hunt and Rodgers 2003).

Tunnel servers: This service may be provided by a VPN router or a firewall. Assigning an existing network component this additional responsibility may have a serious impact on performance (Hunt and Rodgers 2003).

Cryptocards: Encryption algorithms that provide strong encryption, such as 3-DES, are computationally expensive and can limit effective bandwidth to around 100 Mbps unless specialized cryptographic hardware is used. On a workstation, this specialized hardware is provided in the form of an expansion card, which may be separate or integrated with the network interface card. Some firewalls also offer hardware support for various encryption algorithms (Hunt and Rodgers 2003).

PROTOCOLS USED BY VPNs

Point-to-Point Tunneling Protocol

The point-to-point tunneling protocol (PPTP) (Pall et al. 1999) allows the point-to-point protocol (PPP) (Network Working Group 1994), to be tunneled through an IP network. PPTP does not specify any changes to the PPP protocol, but rather describes a new vehicle for carrying PPP. The PPTP network server (PNS) is meant to run on a general-purpose operating system while the client, referred to as a PPTP access concentrator (PAC), operates on a dial access platform. PPTP specifies a call control and management protocol that allows the server to control access for dial-in circuit switched calls originating from a PSTN or ISDN or to initiate outbound circuit-switched connections. A network access server (NAS) provides temporary, on-demand network access to users. This access is point-to-point using PSTN or ISDN lines.

PPTP uses an extended version of the generic routing encapsulation mechanism (Hanks et al. 1994) to carry user PPP packets. These enhancements allow for low-level congestion and flow control to be provided on the

tunnels used to carry user data between PAC and PNS. This mechanism allows for efficient use of the bandwidth available for the tunnels and avoids unnecessary retransmissions and buffer overruns. PPTP does not dictate the particular algorithms to be used for this low-level control, but it does define the parameters that must be communicated in order to allow such algorithms to work (Pall et al. 1999). PPTP allows existing NAS functions to be separated using a client/server architecture. Traditionally, the following functions are implemented by an NAS (Pall et al. 1999):

1. Physical native interfacing to PSTN or ISDN and control of external modems or terminal adapters
2. Logical termination of a PPP link control protocol (LCP) session
3. Participation in PPP authentication protocols
4. Channel aggregation and bundle management for PPP multilink protocol
5. Logical termination of various PPP network control protocols (NCPs)
6. Multiprotocol routing and bridging between NAS interfaces

PPTP divides these functions between the PPTP access concentrator (PAC) and the PNS. The PAC is responsible for functions 1, 2, and possibly 3. The PNS may be responsible for function 3 and is responsible for functions 4, 5, and 6. The decoupling of NAS functions offers the following benefits (Pall et al. 1999):

- *Flexible IP address management.* Dial-in users may maintain a single IP address as they dial into different PACs as long as they are served from a common PNS.
- *Support of non-IP protocols for dial networks behind IP networks.*
- *A solution to the "multilink hunt-group splitting" problem.* Multilink PPP, typically used to aggregate ISDN B channels, requires that all the channels composing a multi-link bundle be grouped at a single NAS. Since a multilink PPP bundle can be handled by a single PNS, the channels comprising the bundle may be spread across multiple PACs.

The PPTP protocol is implemented only by the PAC and PNS. No other systems need to be aware of PPTP. Dial-up networks may be connected to a PAC without being aware of PPTP. Standard PPP client software should continue to operate on tunneled PPP links. PPTP can also be used to tunnel a PPP session over an IP network. In this configuration the PPTP tunnel and the PPP session run between the same two machines with the caller acting as a PNS (Pall et al. 1999).

A tunnel is defined by a PNS-PAC pair. The tunnel protocol is defined by a modified version of GRE. The tunnel carries PPP datagrams between the PAC and the PNS. Many sessions are multiplexed on a single tunnel. A control connection operating over TCP controls the establishment, release, and maintenance of sessions and of the tunnel itself (Pall et al. 1999).

The security of user data passed over the tunneled PPP connection is addressed by PPP, as is authentication of the PPP peers. Because the PPTP control channel messages are neither authenticated nor integrity-protected, it might be possible for an attacker to hijack the underlying TCP connection. It is also possible to manufacture false control channel messages and alter genuine messages in transit without detection. The GRE packets forming the tunnel itself are not cryptographically protected. Because the PPP negotiations are carried out over the tunnel, it may be possible for an attacker to eavesdrop on and modify those negotiations. Unless the PPP payload data are cryptographically protected, it can be captured and read or modified (Pall et al. 1999).

PPTP is limited in usage. It offers remote connections to a single point. It does not support multiple connections, nor does it easily support network-to-network connections. PPTP's security is also limited. It does not offer protection from substitution or playback attacks, nor does it provide perfect forward secrecy. PPTP has no clear mechanism for renegotiation if connectivity to the server is lost (Günter 2001).

Layer Two Tunneling Protocol

Layer two tunneling protocol L2TP (Townesley et al. 1999) facilitates the tunneling of PPP packets across an intervening network in a way that is as transparent as possible to both end users and applications. PPP defines an encapsulation mechanism for transporting multiprotocol packets across layer two (L2) point-to-point links. Typically, a user obtains an L2 connection to an NAS using one of a number of techniques (e.g., dial-up through the telephone system, ISDN, asymmetric digital subscriber line [ADSL], etc.) and then runs PPP over that connection. In such a configuration, the L2 termination point and PPP session end point reside on the same physical device (i.e., the NAS) (Townesley et al. 1999).

L2TP extends the PPP model by allowing the L2 and PPP endpoints to reside on different devices interconnected by a packet-switched network. With L2TP, a user has an L2 connection to an access concentrator (e.g., modem bank, ADSL access multiplexer, etc.), and the concentrator then tunnels individual PPP frames to the NAS. This allows the actual processing of PPP packets to be divorced from the termination of the L2 circuit. One obvious benefit of such a separation is that instead of requiring the L2 connection terminate at the NAS (which may require a long-distance toll charge), the connection may terminate at a (local) circuit concentrator, which then extends the logical PPP session over a shared infrastructure such as frame relay circuit or the Internet. From the user's perspective, there is no functional difference between having the L2 circuit terminate in an NAS directly or using L2TP (Townesley et al. 1999).

L2TP has inherent support for the multiplexing of multiple calls from different users over a single link. Between the same two IP end points, there can be multiple L2TP tunnels, as identified by a tunnel-id, and multiple sessions within a tunnel, as identified by a session-id. Signaling is supported via the built-in control connection protocol, allowing both tunnels and sessions to be established dynamically (Rosenbaum et al. 2003).

L2TP transports PPP packets (and only PPP packets) and thus can be used to carry multiprotocol traffic, since PPP itself is multiprotocol. L2TP also supports sequenced delivery of packets. This is a capability that can be negotiated at session establishment, and that can be turned on and off during a session. Concerning tunnel maintenance, L2TP uses a keepalive protocol in order to distinguish between a tunnel outage and prolonged periods of tunnel inactivity (Rosenbaum et al. 2003).

L2TP as used over IP networks runs over UDP (user datagram protocol) and must be used to carry PPP traffic. This results in a significant amount of overhead both in the data plane, with UDP, L2TP and PPP headers, and in the control plane, with the L2TP and PPP control protocols (Rosenbaum et al. 2003). An L2TP header contains a 1-bit priority field, which can be set for packets that may need preferential treatment during local queuing and transmission. Also by transparently extending PPP, L2TP has inherent support for PPP mechanisms such as multi-link PPP and its associated control protocols, which allow for bandwidth on demand to meet user requirements (Rosenbaum et al. 2003).

Security Considerations

The L2TP tunnel end points may optionally perform an authentication procedure of one another during tunnel establishment. This authentication provides reasonable protection against replay and snooping during the tunnel-establishment process. This mechanism is not designed to provide any authentication beyond tunnel establishment; it is fairly simple for a malicious user to inject packets once an authenticated tunnel has been established successfully (Obaidat and Boudriga 2007; Townesley et al. 1999).

Securing L2TP (Patel et al. 2001) requires that the underlying transport make available encryption, integrity, and authentication services for all L2TP traffic. This secure transport operates on the entire L2TP packet and is functionally independent of PPP and the protocol being carried by PPP. As such, L2TP is concerned only with confidentiality, authenticity, and integrity of the L2TP packets between its tunnel end points. L2TP is similar to PPTP, and they both target the remote access scenario. L2TP delegates security features toward IP Security (IPsec), which is presented later in this chapter. Also, it suffers from the same drawbacks as PPTP (Günter 2001).

The choice between PPTP and L2TP for deployment in a VPN depends on whether the control needs to lie with the service provider or with the subscriber (Ferguson and Huston 1998). Indeed, the difference can be characterized as to the client of the VPN, in which the L2TP model is one of a "wholesale" access provider who has a number of configured client service providers who appear as VPNs on the common dial-up access system, while the PPTP model is one of distributed private access, in which the client is an individual end user and the VPN structure is that of end-to-end tunnels. One might also suggest that the difference is also a matter of economics, since the L2TP model allows the service provider to actually provide a value-added service, beyond basic IP-level connectivity, and charge their subscribers accordingly for the privilege of using it, thus creating new revenue streams.

On the other hand, the PPTP model enables distributed reach of the VPN at a much more atomic level, enabling corporate VPNs to extend access capabilities without the need for explicit service contracts with a multitude of network access providers (Ferguson and Huston 1998).

IP Security

IP security (IPSec) is an open architecture for IP-packet encryption and authentication, thus it is located in the network layer (Man 2003). IPSec adds further headers/trailers to an IP packet and can encapsulate (tunnel) IP packets in new ones (Cohen 2003). A number of security services are provided by IPSec, including access control, connectionless integrity, nonrepudiation, protection against replay attacks, confidentiality, and limited traffic flow confidentiality. These services are provided at the transport layer, offering protection for IP and upper-layer protocols (Hunt and Rodgers 2003). There are three main functionalities of IPSec, separated into three protocols—authentication through an authentication header (AH), encryption through an encapsulating security payload (ESP), and automated key management through the Internet key exchange (IKE) protocol. IPSec provides an architecture for key management, encryption, authentication, and tunneling (Cohen 2003). IPSec was designed to be algorithm-independent. It supports several encryption and authentication algorithms, which allow the companies using VPN to select the desired security level for each VPN (Obaidat and Boudriga 2007; Younglove 2000).

IPSec is an optimal solution for trusted LAN-to-LAN VPNs (Günter 2001). IPsec can ensure authentication, privacy, and data integrity. It is open to a wide variety of encryption mechanisms. It is application-transparent and a natural IP extension, thus ensuring interoperability among VPNs over the Internet. Router vendors and VPN hardware vendors support IPsec. Nevertheless, there are disadvantages of IPsec. It is bound to the TCP/IP stack. IP addressing is part of IPsec's authentication algorithm. This is less secure than higher-layer approaches, and it is a problem in dynamic address environments, which are common to ISPs. Moreover, it requires a public key infrastructure, which is still subject to current research, and it does not specify a method for access control beyond simple packet filtering (Günter 2001).

The Encapsulating Security Payload

The encapsulating security payload (ESP) protocol is responsible for packet encryption. An ESP header is inserted into the packet between the IP header and the packet contents. The header contains a security parameter index (SPI), which specifies to the receiver the appropriate security association (SA) for processing the packet. Also included in the ESP header is a sequence number that is a counter that increases each time a packet is sent to the same address using the same SPI and that indicates the number of packets that have been sent with the same group of parameters. The sequence number provides protection against replay attacks, in which an attacker copies a packet and sends it out of sequence to confuse communicating nodes. Packet data are encrypted prior to transmission. ESP allows multiple methods of encryption,

with DES as its default. ESP also can be used for data authentication. Included in the ESP header is an optional authentication field, which contains a cryptographic checksum that is computed over the ESP packet when encryption is complete. The ESP's authentication services do not protect the IP header that precedes the ESP packet.

ESP can be used in two different modes. In transport mode, the packet's data, but not the IP header, are encrypted and, optionally, authenticated. Although transport-mode ESP is sufficient for protecting the contents of a packet against eavesdropping, it leaves the source and destination IP addresses open to modification if the packet is intercepted. In tunnel mode, the packet's contents and the IP header are encrypted and, optionally, authenticated. Then, a new IP header is generated for routing the secured packets from sender to receiver. Although tunnel-mode ESP provides more security than transport-mode ESP, some types of traffic analysis are still possible. For example, the IP addresses of the sending and receiving gateways could still be determined by examining the packet headers (Obaidat and Boudriga 2007).

Key Management

There are two ways to handle key management within IPSec's architecture: manual keying and Internet key exchange. Manual keying involves face-to-face key exchanges (e.g. trading keys on paper or magnetic disk) or sending keys via a bonded courier or e-mail. Although manual keying is suitable for a small number of sites, automated key management is required to accommodate on-demand creation of keys for SAs. IPSec's default automated key management protocol is Internet key exchange (IKE), which was formed by combining the Internet security association key management protocol (ISAKMP), which defines procedures and packet formats to establish, negotiate, modify, and delete SAs, with the Oakley key determination protocol, which is a key exchange protocol based on the Diffie-Hellman algorithm (Diffie and Hellman 1976).

Because key exchange is closely related to the management of SAs, part of the key-management procedure is handled by SAs, and the SPI values that refer to the SAs, in each IPSec packet. Whenever an SA is created, keys must be exchanged. IKE's structure combines these functions by requiring the initiating node to specify:

- an encryption algorithm to protect data
- a hash algorithm to reduce data for signing
- an authentication method for signing the data
- information about the material needed to generate the keys, over which a Diffie-Hellman exchange is performed

A pseudo-random function used to hash certain values during the key exchange for verification purposes may also be specified.

Packet Authentication

In IPSec's architecture, the AH provides data integrity and authentication services for IP packets. The data integrity feature prevents the undetected modification of a packet's

contents while the packet is in transit, and the authentication feature prevents address spoofing and replay attacks, and enables the receiver to authenticate the application and filter traffic accordingly (Wright 2000). Like the ESP header, the AH is inserted into the packet between the IP header and the packet contents. The AH also contains an SPI, which specifies to the receiver the security protocols the sender is using for communications. The authentication provided by the AH differs from that provided by the ESP. AH services protect the external IP header that precedes the ESP header, along with the entire contents of the ESP packet. The AH contains authentication data, obtained by applying the hash algorithm defined by the SPI to the packet's contents. Two algorithms are supported: hash-based message authentication code with message digest version 5 (HMAC-MD5) and secure hash algorithm version 1 (SHA-1) (Wright 2000).

The AH can be used in the same two modes as ESP. In transport mode, the packet's data and the original IP header are authenticated. In tunnel mode, the entire IP packet—data, original IP header, and outer IP header—are authenticated. In addition to applying either AH or ESP to an IP packet in transport or tunnel modes, IPsec supports combinations of these modes. Several combinations are possible, among them (Wright 2000):

- ESP could be used in transport mode without the authentication option (to encrypt the packet's data), then AH could be applied in transport mode (to authenticate the ESP header, the packet's data, and the original IP header).
- AH could be used in transport mode to authenticate the packet's data and the original IP header, then ESP could be applied in tunnel mode to encrypt the entire, authenticated inner packet and to add a new IP header for routing the packet from sender to receiver.
- ESP could be used in tunnel mode to encrypt and, optionally, authenticate a packet and its original header, then AH could be applied in transport mode to authenticate the packet's data, original IP header, and outer IP header.

User Authentication

A VPN must be able to reliably authenticate users in order to control access to enterprise resources and keep unauthorized users out of corporate networks (Wright 2000). Three protocols are described here: PAP, CHAP, and RADIUS.

Password Authentication Protocol. The password authentication protocol (PAP) was originally designed as a simple way for one computer to authenticate itself to another computer when PPP is used as the communication's protocol. PAP is a two-way handshaking protocol. When the PPP link is established, the client system sends the plaintext user ID and password pair to the destination system (the authenticator). The authenticator either accepts the pair or terminates the connection. PAP is not a secure means of user authentication. The authentication information is transmitted in the clear, and there is nothing to protect against playback attacks or excessive

attempts by attackers to guess valid user ID/password pairs (Wright 2000).

Challenge Handshake Authentication Protocol. The challenge handshake authentication protocol (CHAP) is a more secure method for authenticating users. CHAP is a three-way handshaking protocol. Instead of the simple, two-step user ID/password approval process used by PAP, CHAP uses a three-step process to produce a verified PPP link (Wright 2000):

- The authenticator sends a challenge message to the client system.
- The client system calculates a value using a one-way hash function and sends the value back to the authenticator.
- The authenticator acknowledges authentication if the response matches the expected value.

CHAP removes the possibility that an attacker can try repeatedly to log in over the same connection (a weakness inherent in PAP). However, PAP and CHAP share some disadvantages. Both protocols rely on a secret password that must be stored on the remote user's computer and the local computer. If either computer comes under the control of a network attacker, the password will be compromised. Also, both PAP and CHAP allow only one set of privileges to be assigned to a specific computer. This prevents different network access privileges from being assigned to different remote users who use the same remote host (Wright 2000).

Remote Authentication Dial-In User Service. The remote authentication dial-in user service (RADIUS) protocol provides greater flexibility for administering remote network connection users and sessions. RADIUS uses a client/server model to authenticate users, determine access levels, and maintain all necessary auditing and accounting data. The RADIUS protocol uses an NAS to accept user connection requests, to obtain user ID and password information, and to pass the encrypted information securely to the RADIUS server. The RADIUS server returns the authentication status (approved or denied), along with any configuration data required for the NAS to provide services to the user. User authentication and access to services are managed by the RADIUS server, enabling a remote user to gain access to the same services from any communications server that can communicate with the RADIUS server (Obaidat and Boudriga 2007; Wright 2000).

The services and protocols of IPsec are summarized in Figure 4.

SOCKS v5 and Secure Sockets Layer

SOCKS v5 was originally approved by the IETF as a standard protocol for authenticated firewall traversal (Günter 2001). When combined with the secure sockets layer (SSL) it provides the foundation for building highly secure VPNs that are compatible with any firewall. SOCKS v5's strength is access control; it controls the flow of data at the session layer (open system interconnection [OSI] layer 5). It establishes a circuit

Figure 4: Summary of IPsec (MD-5 = message-digest algorithm 5; PAP = password authentication protocol; SHA = secure hash algorithm)

between a client and a host on a session-by-session basis. Thus, it can provide more detailed access control than protocols in the lower layers without the need to reconfigure each application. SOCKS v5 and SSL can interoperate on top of IPv4, IPsec, PPTP, L2TP, or any other lower-level VPN protocol. A session-layer solution does not have to interfere with the networking transport components; thus, the clients are nonintrusive. SOCKS v5 provides plug-and-play capabilities, including access control, protocol filtering, content filtering, traffic monitoring, reporting, and administration applications. On the minus side, SOCKS v5 decreases performance. Also, client software is required to build a connection through the firewall to transmit all TCP/IP data through the proxy server (Günter 2001).

Multiprotocol Label Switching

Multiprotocol label switching (MPLS) is deployed in an ISP's IP backbone network that uses IP routers at the edges of the network and ATM switches controlled by an MPLS component in the inside (Günter 2001). The basic idea is to do (intelligent) layer three routing at the edges of the backbone network and to do fast layer two forwarding inside the backbone network. Incoming IP packets get an attached MPLS header, they are labeled according to IP header information (mainly the target address, but also type of service and other fields). A label switched path is set up for each route or path through the network. Once this is done, all subsequent nodes may simply forward the packet along the label-switched path identified by the label at the front of the packet. Negotiations of labels between nodes are done by the label distribution protocol of MPLS. An ATM connection is set up for each label-switched path. Thus, MPLS can support quality of service. MPLS makes the underlying backbone infrastructure invisible to the layer three mechanisms. This lightweight tunneling provides an extendable foundation that provides VPN and other service capabilities. Furthermore, the MPLS architecture enables network operators to define explicit routes

(Günter 2001). MPLS technologies are useful for ISPs that want to offer their customers a wide band of IP services. The ISPs add value to their service, for example, by offering the complete management of the customers' VPN. Obviously, the more the customers outsource their VPN management, the more crucial network management becomes to the ISP (Günter 2001).

MPLS VPNs provide a highly scalable technology for ISPs that want to offer layer three VPN services to their customers (Chou 2004). BGP-4 (Rekhter, Watson and Li 1995) is a scalable protocol and is widely accepted in the industry. Furthermore, it is also very well-suited to carrying additional information in its routing updates, which is required in the MPLS VPN architecture (Obaidat and Boudriga 2007; Tomsu and Wieser 2002).

QUALITY-OF-SERVICE SUPPORT

Apart from creating a segregated address environment to allow private communications, there is also the expectation that the VPN environment will be in a position to support a set of service levels (Zeng and Ansari 2003; Braun et al. 1999). Such per-VPN service levels may be specified either in terms of a defined service level on which the VPN can rely at all times, or in terms of a level of differentiation that ensures that the VPN can draw on the common platform resource with some level of priority of resource allocation (Ferguson and Huston 1998). Efforts within the Integrated Services Working Group of the IETF have resulted in a set of specifications for the support of guaranteed and controlled load end-to-end traffic profiles using a mechanism that loads per-flow state into the switching elements of the network. There are a number of caveats regarding the use of these mechanisms, in particular relating to the ability to support the number of flows that will be encountered on the public Internet. Such caveats tend to suggest that these mechanisms will not be the ones ultimately adopted to support service levels for VPNs in very large networking environments (Ferguson and Huston 1998).

The differentiated services (DiffServ) approach tries to provide a solution for quality of service (QoS) support with better scalability than integrated services (IntServ). Differentiated services can provide two or more QoS levels without maintaining per-flow state at every router. The idea of the DiffServ approach is to use the DiffServ field in the IP header to designate the appropriate DiffServ level that the packet should receive. DiffServ can provide scalability by aggregating the flows into a small number of DiffServ classes and by implementing traffic conditioning at the boundary routers of a network or an administrative domain (Cohen 2003).

It must be noted that QoS and VPN techniques introduce new challenges. They need extensive configurations in the routers. The local configurations have to be consistent across the network. Many companies may not have the knowledge and resources to deploy and manage enhanced Internet services by themselves. Rather, they will outsource the service management to their ISP (Braun, Günter, and Khalil, 2001).

The traditional model for specifying QoS arrangements involves drawing a set of network service requirements between ordered pair of customer sites. The ordered pair defines a direction of data flow, and the whole set is termed the "traffic matrices." The traffic matrices model gives the customer fine granularity of control over the traffic flows between customer sites, and the network provider can offer stringent service guarantee for each data flow. However, maintaining the traffic matrices can become complicated as the VPN grows in size (Harding 2003).

Recent developments in VPN technologies have introduced a new QoS specification model, called the "hose model," that may be desirable to the VPN customers (Kumar et al. 2002). In this model, two hoses are given to the customer with one hose used for sending traffic out of the network and the other used for receiving traffic from the network. This means that the network provider offers aggregate traffic service in which all traffic going toward the customer site must fit within the receiving hose capacity and all the traffic going out of the customer site must be within the sending hose capacity (Harding 2003). The hose specification contains the egress bandwidth (outbound traffic) and the ingress bandwidth (inbound traffic) pair for every customer site that takes part in the VPN. The major advantages of this model from the customer's perspective are that specification is made simple and there is a high potential for multiplexing gain for using aggregate requirements rather than traffic matrices. The simple specification allows changes to be made easily, including changes in the VPN membership. However, the customer in this model loses control of the data flow between sites, and the service guarantee is on an aggregate basis, resulting in a coarser service guarantee level (Harding 2003). From a network provider's perspective, the traffic matrices model specifies heavy constraints, which restrict the network optimization that can be achieved. The hose model specifies aggregate requirements that are lighter in constraints, thus giving the network provider more flexibility to perform network optimization. Network optimization involves mechanisms to improve bandwidth efficiency, load balancing, and traffic multiplexing (Harding 2003).

CONCLUSION

People increasingly depend on remote access to do their jobs, and demand is growing for access to large volumes of corporate information. Moreover, the upsurge of e-commerce means that companies are implementing business applications that share information among sites, extending the reach of their business to partners, contractors, and supply chain. In all these areas, VPNs promise to reduce recurring telecommunications charges, minimize the amount of access equipment required, and give managers better control over their networks (Younglove 2000). Organizations are struggling to meet the escalating demand for remote connectivity, and they are having difficulty dealing with the resulting increase in network complexity and end-user support costs. VPNs offer a more affordable, scalable way to meet the demands of a growing community of remote users and to manage branch office connectivity. They can help to accommodate the pace and unpredictability of business by linking customers and business partners into extranets on an ad hoc basis. VPNs can provide access to networked resources without compromising security. Virtual private networking offers the capability of enhanced and secure corporate communications, with the promise of future cost savings (Wright 2000).

The pertinent conclusion here is that while a VPN can take many forms, there are some basic common problems that a VPN is built to solve. These are virtualization of services and segregation of communications to a closed community of interest, while simultaneously exploiting the financial opportunity of economies of scale of the underlying common host communications system. Each solution has a number of strengths and also a number of weaknesses and vulnerabilities. There is no single mechanism for VPNs that will supplant all others in the months and years to come, but instead we will continue to see a diversity of technology choices in this area of VPN support (Ferguson and Huston 1998).

GLOSSARY

Border Gateway Protocol (BGP): A routing protocol that facilitates the exchange of network reachability information between systems.

Challenge Handshake Authentication Protocol (CHAP): A three-way handshaking authentication protocol that can be applied to produce a verified PPP link. CHAP is a more secure authentication protocol than PAP.

Extranet VPN: A VPN that extends limited access to corporate computing resources to business partners, such as customers or suppliers.

Generic Routing Encapsulation (GRE): A simple, general purpose encapsulation mechanism.

Internet Key Exchange (IKE): The default automated key management protocol of IPSec.

Intranet VPN: A VPN that connects a number of local area networks located in multiple geographic areas over a shared network infrastructure.

IP Security (IPSec): An open architecture for IP-packet encryption and authentication, and key management.

IPSec adds additional headers/trailers to an IP packet and can encapsulate (tunnel) IP packets in new ones.

Layer Two Tunneling Protocol (L2TP): A tunneling protocol that facilitates the tunneling of PPP packets across an intervening network in a way that is as transparent as possible to both end users and applications.

Network Address Translation (NAT): A method by which IP addresses are mapped from one address realm (i.e., network domain) to another, providing transparent routing to end hosts.

Password Authentication Protocol (PAP): A simple two-way handshaking authentication protocol that allows one computer to authenticate itself to another computer when the point-to-point protocol is used as the communication's protocol.

Point-to-Point Protocol (PPP): A protocol that defines an encapsulation mechanism for transporting multiprotocol packets across layer two point-to-point links.

Point-to-Point Tunneling Protocol (PPTP): A tunneling protocol used by VPNs that allows the point-to-point protocol to be tunneled through an IP network.

Remote-Access VPN: A VPN that connects telecommuters and mobile users to corporate networks.

Remote Authentication Dial-In User Service (RADIUS): A user authentication protocol that uses a client/server model to authenticate users, determine access levels, and maintain all necessary audit and accounting data.

Virtual Private Network (VPN): A private network constructed within a public network infrastructure, such as the global Internet.

INTRODUCTION

For most people, the word *cryptography* evokes one of two images. There is the classical, somewhat outdated idea of crabbled documents, full of symbols, tucked into books or carried by spies on microfiche. Then there is the updated notion of computers performing arcane calculations that protect everything from secrets of state to credit-card numbers. Both ideas have an element of truth. Indeed, the word *cryptography* derives from the Greek for “secret writing.” Today, however, the science of cryptography has overflowed its etymological confines, and means much more than the mere transmission of secret messages and concealment of data. Cryptography, in its fullest contemporary sense, is the science of communicating in the presence of adversaries. To put it another way, cryptography is about enforcing fair play in information exchange in potentially hostile environments.

A couple of examples help illustrate the broad scope of the field. Consider two people, Alice and Bob. (Alice and Bob are the stock characters of storytelling among cryptographers—i.e., scientists who study cryptography.) Alice and Bob each have a list of favorite movies, denoted A and B , respectively. Together they would like to determine which favorite movies they have in common—that is, the intersection $A \cap B$. They do not want to reveal their full lists to one another, however, as they consider these lists to be highly personal. Alice and Bob’s goal here is indeed to keep information hidden, as in the classical view of cryptography; however, they also want to reveal information to one another on a selective basis. If you take a moment to reflect on how Alice and Bob can together learn $A \cap B$ without revealing any other data to one another, you may well find it far from obvious. It may even seem impossible without outside help. Contemporary cryptographic techniques, however, make such tasks possible. In fact, tasks like privacy-preserving partial matching of lists are useful in a variety of fields. Health care is one example; a group of hospitals may wish to know the names of any patients making multiple (fraudulent) insurance claims, but are not at liberty to disclose their patient lists to one another.

Here is another example. Alice is sending e-mail to Bob regarding a large financial transaction. She is concerned that her e-mail could be altered in transit or by unscrupulous people in Bob’s office. (Even the change of a single digit, e.g., a change from \$100,000 to \$1,000,000 could, of course, have very serious implications.) Alice would like to ensure that her message is secure against tampering. A cryptographic tool called a “digital signature”—supported, in fact, in many e-mail clients—can achieve exactly this goal, and ensure the integrity of Alice’s message to Bob.

At a broader level, the design of electronic voting systems—polling-site machines and apparatus for central tabulation—poses an instructive collection of surprisingly formidable cryptographic challenges. The underlying goal is easy to state. A voting system should permit every registered voter to cast a single, private vote, and should yield a certifiably correct tally. Mechanical systems to accomplish this goal have existed since the classical period of Greek history. In an electronic environment, however, many complications arise. For example, many polling sites today use computers that allow voters to input their choices on touch screens and output a local tally at the end of the voting period. But how can voters be assured that these machines operate correctly? It is easily conceivable that in a race between candidate A and candidate B that an electronic voting machine could be programmed (either accidentally or with malicious intent) to discard half of the votes cast for candidate A . Indeed, experts have noted grave concerns about existing voting systems, and have proposed a range of cryptographic solutions. Here again, cryptography can achieve an almost paradoxical proposition. It permits the creation of a system in which voters’ choices remain anonymized, but the system yields a publicly verifiable, mathematical proof of correctness of a centralized tally.

These examples illustrate the very broad purview of cryptography and its relevance not merely in military and diplomatic circles, but to everyday users of computing systems. As I explain, strong cryptographic algorithms are present in the basic software of nearly every computer sold

today, and play a large, if often hidden role, in e-commerce and basic computer security. Often without knowing it, active users of the Internet use encryption to conceal data on a regular basis. When accepting credit-card information or processing other financial transactions, most Web servers initiate encryption sessions with clients. The form of encryption used to support sessions of this kind on the Web is very strong—so strong that it is generally believed to be effectively unbreakable by even the most powerful computers. In most browsers, the appearance of an icon representing a closed padlock on the bottom of the screen indicates the use of encryption in a protocol known as SSL (secure sockets layer). By clicking on this padlock, a user can learn detailed information about the encryption session, much of which is explained in further depth in this chapter.

Although the science of constructing systems to protect data is called “cryptography,” the science of analyzing and attempting to find weaknesses in cryptographic systems is called “cryptanalysis.” Together, the two complementary sciences are known as cryptology. In this chapter, I focus mainly on encryption, one of the most widespread applications of cryptography, and in many respects the most accessible. (I draw heavily on my chapter, entitled “Encryption,” published in the *Handbook of Information Security* [Juels 2006]). I also briefly discuss digital signatures and data integrity. For readers interested in more advanced applications of cryptography, I suggest the further readings at the end of this chapter.

A Brief Historical Note

An exciting subject of study in its own right, the history of cryptography—and cryptology—is also intimately associated with the birth of the digital computer. During WWII, the efforts of British signals intelligence to break the German Enigma cipher led to the development of mechanical devices known as “bombes,” so called because of the ticking sounds they made in testing possible cipher keys. The bombes and the later generation of Colossus machines arising from these efforts were important precursors of the modern computer. Moreover, the man overseeing the immensely successful Enigma break was Alan Turing, a progenitor of the field of computer science.

SYMMETRIC-KEY CRYPTOGRAPHY

Encryption is the most basic and historically important operation in the field of cryptography. It is the procedure of rendering a message into a concealed form so that it is decipherable exclusively by a particular recipient or recipients. The message in its original state is known as a *plaintext* (or *cleartext*); in its encrypted form, it is known as a *ciphertext*. Historically, the aim of encryption has been to enable two parties to exchange messages confidentially, even in the presence of an eavesdropper capable of intercepting most or all of their communications. The use of encryption has been confined chiefly to diplomatic and military circles in the past, but its scope in everyday life has broadened enormously in recent years. Thanks to the rise of the Internet, it is estimated that over half a billion personal computers are equipped today with strong

encryption capabilities in their Web-browsing software. This includes nearly every new computer sold today.

An encryption algorithm is considered to be secure when an adversary—traditionally referred to in cryptographic circles as Eve—cannot feasibly distinguish between the encryptions of two different plaintexts. This should hold even in cases in which Eve has the ability to manipulate the messages transmitted between Alice and Bob in various ways. For example, suppose that Eve can cause Alice to generate and reveal ciphertexts A and B computed on messages X and Y in a random order. Eve should nonetheless be unable to tell whether A is an encryption of X or of Y .

The operational basis of an encryption algorithm, or cipher, is a piece of information known as a key. A key serves as input to the encryption process that Alice and Bob have agreed to use. The encryption process consists of a series of instructions on how Alice, for instance, should convert a plaintext into a ciphertext. The key serves as a parameter guiding the instructions. The reverse process, whereby Bob converts a ciphertext back into a plaintext, is also guided by a key, one that may or may not be the same as Alice’s. The security of traditional ciphers—that is, the privacy of the messages they encrypt—depends on a shared key that is kept secret. For example, in one form of folklore encryption, Alice and Bob each have copies of the same edition of a particular novel. They share the identity of this novel as a secret between them. Alice encrypts a plaintext by finding a random example of each letter of her message in the novel. She writes down the page, line, and ordinal position of each of these letters in turn. The result of this process constitutes the ciphertext. Bob, of course, can reverse the process and obtain the original plaintext by referring to his copy of the shared novel. In this case, the novel itself serves as a key—one that is quite long, of course, running potentially to hundreds of pages. In the forms of cryptography used on computers today, the key is much shorter, typically equivalent in length to several words or sentences.

Symmetric-Key Encryption

When Alice and Bob make use of the same key for encryption and decryption, as in our example above, this is referred to as symmetric encryption, or symmetric-key encryption. Figure 1 gives a basic operational schematic of symmetric-key encryption.

Let us consider another folklore cipher, in which each letter of a message is replaced with another letter according to a fixed set of random, predetermined assignments. For example, the message, “MEET ME UNDER THE BRIDGE” might be encrypted as: ZKKO ZK BWIKQ OPK UQMIFK.

This form of encryption is known as a substitution cipher. It is, in fact, quite easy for a skilled cryptanalyst—or even just a good puzzle solver—to break. Edgar Allen Poe, for instance, challenged readers of a newspaper in 1839 to submit English-language ciphertexts produced by letter substitution. He published the plaintexts of many such challenge ciphertexts in subsequent issues of the newspaper. Knowing, for example, that e is the most common letter in the English language, one would be tempted—quite

Figure 1: Symmetric-key encryption. Bob wishes to transmit plaintext message m securely to Alice over a channel subject to eavesdropping. He encrypts it under shared symmetric key k to obtain ciphertext c , and transmits c . Eavesdropper Eve learns the ciphertext c , but should not learn m if the cipher is constructed and used properly

correctly—to identify the letter K , which appears most frequently in the above ciphertext, with the letter e in the plaintext. More sophisticated cryptanalytic techniques for attacking substitution ciphers focus on the frequency statistics not just for single letters, but also for letter pairs and triples.

Knowing that their cipher is subject to cryptanalytic attacks of this kind, Alice and Bob might be tempted to use a different, perhaps more complex cipher, and to hide from Eve not just their key, but also the workings of the cipher. This is equivalent in effect to making the choice of the cipher a part of the key itself. An important principle enunciated by the nineteenth-century cryptologist Auguste Kerckhoffs (1883) discourages this approach. Adhered to by contemporary cryptologists, this principle may be stated as follows: The security of a cipher should reside in the key alone, not in the secrecy of the process of encryption. The motivations behind Kerckhoffs's principle are several. First of all, widespread use of a good cipher requires that its workings be divulged in some form. Even if a cipher is disseminated only through software, for example, the underlying instructions can be reverse-engineered. Thus, it is fair to assume that an attacker can learn the mechanics of the cipher. Moreover, despite the oft-demonstrated inventiveness of the cryptographic community, there is time enough to devise and refine only a limited number of basic techniques for strong new ciphers. A poorly designed cipher, even when its workings are hidden from view, is vulnerable to attack by means of an arsenal of analytic techniques refined by the cryptanalytic community over many years. These techniques are roughly analogous in spirit to the idea that leads to the discovery of the letter e in the example ciphertext above, but rely on more sophisticated forms of statistical analysis.

The basic unit of information in the computer and the fundamental unit for the encoding of digital messages is not the letter, but the bit. For this reason, contemporary symmetric-key ciphers operate through the manipulation of bits, rather than lexicographic units. One of the earliest ciphers designed from this perspective is known as the one-time pad. Invented during World War I, the one-time pad is also of interest as the only cipher whose security is provable in the strictest mathematical sense. Formal understanding of its properties emerged in 1948–1949, with the publication of seminal work by Claude Shannon (1948). (The security analysis of other ciphers, as I shall explain, has a strong, but less complete or rigorous mathematical basis).

A one-time pad is a key shared by Alice and Bob consisting of a perfectly random string of bits as long as the message that Alice wishes to transmit to Bob. To encrypt her message, Alice aligns the pad with the message so that there is a one-to-one correspondence between the bits in both. Where the pad contains a 1, Alice flips the corresponding bit in her plaintext. She leaves the other bits of the plaintext unchanged. This simple process yields the ciphertext. As may be proven mathematically—and perhaps grasped intuitively—this ciphertext is indistinguishable to Eve from a completely random string. Indeed, from her perspective, it is a completely random string. This is to say that Eve can learn no information at all from the ciphertext, no matter how powerful her cryptanalytic capabilities. Apart from its requirement of perfect randomness, though, the one-time pad carries another strong caveat. The term *one-time* refers to the fact that if Alice uses the same key to encrypt more than one message, she loses the security properties of the cipher. This makes the one-time pad impractical for most purposes, as it requires that Alice and Bob generate, exchange, and store many random bits in advance of their communications. Nonetheless, the one-time pad has seen practical use. For example, the “hot-line” established between the United States and the Soviet Union in the wake of the Cuban missile crisis used a one-time pad system to ensure confidentiality, with tapes containing random keying material exchanged via the embassies of the two countries.

Symmetric-Key Encryption in Practice

The symmetric-key ciphers in common use today are designed to use relatively short keys, typically 128 to 256 bits in length. Moreover, these ciphers retain their security properties even when individual keys are used to encrypt many messages over long periods. Indeed, a well-designed symmetric-key cipher should permit only one effective avenue of attack, described by cryptographers as “exhaustive search” or “brute force.” By this, it is meant that an attacker familiar with the cipher makes random guesses at the key until successful. If Eve wishes to mount a brute-force attack against a ciphertext sent by Alice to Bob, she will repeatedly guess their shared key and try to decrypt the message, until she obtains the correct plaintext.

Given use of a 128-bit-long key, Eve will on average have to make well more than a trillion trillion trillion

guesses before she is successful! This is more, for example, than the total number of atoms composing all of the human beings in the world. The most powerful computers available today could not be expected to mount a successful brute-force attack against a well-designed cipher using a key of this length, even over the course of many years. It should be observed that the difficulty of breaking a key doubles for every additional bit in length. Thus, for instance, a 128-bit key is not twice as hard to break as a 64-bit key, but over a million trillion times harder.

The first widely embraced cipher using the strong design principles in use today was the data encryption standard, or DES (pronounced “dehzh”). Developed at IBM, the DES cipher was published as a federal standard in 1976 by what is now the National Institute of Standards (NIST) of the U.S. government. DES and security-enhanced variants are still widely deployed, particularly in the banking industry. DES uses a 56-bit key, operating on a basic unit of encryption consisting of a 64-bit block. This is to say that in order to encrypt a long message using DES, Alice first subdivides the message into 64-bit (i.e., 8-byte) blocks, each of which she enciphers individually. Ciphers that operate in this fashion are referred to as block ciphers.

Brute-force attack on a 56-bit key requires substantial computational effort, very likely beyond the reach of most organizations at the time of invention of DES. Today, however, such capability is attainable with networks of ordinary workstations. This was first demonstrated in 1997, when a successful attack was mounted against a DES-encrypted ciphertext by a network of thousands of computers over the course of 39 days, and subsequently duplicated by a single, special-purpose computer in less than a day. (It should be noted that even today, DES is still not easy to break without considerable resources.) Earlier concerns about the strength of DES had already prompted many organizations to use a strengthened version involving application of DES operations not once, but three times to each input block, and typically using two distinct DES keys. Known as triple-DES (3-DES), this enhanced version offers considerably stronger security than DES, with what may be viewed as an effective key strength of up to 112 bits.

With DES in its basic form approaching the end of its serviceable lifetime, the cryptographic community began in 1999 to lend its efforts to the development of a new standard cipher to serve as a successor. The advanced encryption standard, or AES (pronounced letter by letter), emerged as the result of an open competition conducted by NIST. After a period of rigorous scrutiny by the research community and government agencies, a cipher known as Rijndael (of which one recognized pronunciation is “Rhine dahl”) was selected as the AES. Designed by two Belgian researchers, Joan Daemen and Vincent Rijmen, the AES is seeing internationally widespread deployment. Rijndael is a block cipher designed to accommodate key lengths of 128, 196, or 256 bits and operate on data blocks of 128, 196, or 256 bits in any of the nine possible combinations. In its standardization as the AES, however, only a 128-bit data block size is accommodated. Rijndael, like many contemporary symmetric-key ciphers, is capable of very fast encryption—easily supporting broadband connection

speeds on typical PCs. The code sizes for AES implementations can be less than 1 kb. The size of a basic ciphertext yielded by AES, as with any block cipher, is roughly the size of the plaintext. A little extra space—less than the block size—may also be needed to accommodate added randomness and the fact the plaintext generally cannot be divided into data blocks of exactly the right size.

Another symmetric-key cipher deserving discussion is RC4. RC4 was designed by Ronald L. Rivest, one of the co-inventors of the RSA cryptosystem, which I discuss later in this chapter. The letters *RC* stand for “Ron’s code,” and the number 4 denotes Rivest’s fourth cipher design. In contrast to the block ciphers described above, RC4 is known as a stream cipher. It does not operate by encrypting individual blocks of data. Rather, the only fixed-length input to RC4 is a key, typically 128 bits in length. The output of the cipher is a string of random-looking bits that serves to encrypt messages. This string may be made as long as desired by the user. In order to encrypt a message for Bob, Alice inputs a shared key to RC4 and generates a string as long as the message. Although not a one-time pad, this string is used by Alice to encrypt the message in exactly the same manner as a one-time pad—that is, using the same system of bit alignment and flipping. In addition, the output string of RC4 for a particular key has the “one-time” restriction, which is to say that the string can be safely used for encryption only once. The fact that RC4 can generate a string of arbitrary length, however, means that different portions of the string can be used for different messages. Also, encipherment under RC4 is naturally capable of yielding a ciphertext identical in length to the plaintext.

This said, the output string of RC4 on a given key is not in fact a one-time pad, because it is not fully random. This may be seen in the fact that Alice and Bob know the process that generated the string, because they know their shared input key to RC4. In particular, they can write a short set of instructions describing to someone else how to generate exactly the same output string from RC4. If k denotes their shared key, these instructions would simply say, “Give the key k as input to RC4.” They could not do this in the case of a truly random string. Suppose, for instance, that Alice and Bob generated a shared random string—that is, a one-time pad—by flipping a coin many times. If they gave the instructions “Flip a coin” to Carol, it is almost certain that Carol, in following the same instructions, would generate a very different-looking string. Obviously, though, RC4 is much more convenient for Alice and Bob to use than a one-time pad, because it requires of them only that they share a key of, say, 128 bits in length. For all intents and purposes, this is true no matter how long the messages they wish to encrypt.

The security of the RC4 cipher comes from the fact that from the perspective of Eve, who does not know the key, the output of RC4 is indistinguishable from a one-time pad. That is, if Alice were to give an RC4 output string to Eve (rather than using it for encipherment), and were also to give Eve a truly random string of the same length, Eve would not be able to tell the difference. Thus, as far as Eve is concerned, when Alice and Bob encrypt their messages using RC4, they might as well be using a one-time pad. This, at any rate, is a rough expression of the

conclusion that cryptanalysts have arrived at after many years of statistical study of the RC4 cipher. They express this belief by describing the output of RC4 as being pseudo-random. Strong block ciphers like AES are also believed to possess this property of pseudo-randomness, but in a different form.

RC4 is of particular interest because it is one of the most commonly used ciphers in the world and included in the software of nearly every new PC sold today. It is generally a component of the SSL encryption system used for secure credit-card transactions on the Internet. In other words, the closed padlock on a browser screen mentioned earlier in this chapter indicates that the RC4 cipher is being used.

The design principal for RC4, like that of most symmetric ciphers, is a delicate sequencing of a few very basic mathematical instructions. In RC4, the operations are the swapping of integer elements in a small array representing a permutation and addition of small integers (in fact, modular addition, an operation explained later in this chapter). Others of Rivest's suite of cipher designs are also in common use, namely RC2, which forms the basis of many e-mail encryption programs, and also RC5. Apart from DES, 3-DES, AES, and the RC series, there are a number of other popular ciphers used in various systems today. These include IDEA, CAST-128, and Blowfish, to name just a few.

Encryption and Passwords

Symmetric-key ciphers are used not only to protect communications, but also commonly to protect files against unauthorized access. Many users rely on encryption software to protect files on their hard drives against exposure to hackers or to protect sensitive data in case of laptop theft. For these purposes, it is common for the user to use a password. The encryption software converts this password into a key for use with a standard symmetric-key cipher such as AES. Because users typically use passwords consisting of or closely related to words in their native languages, there is generally less randomness in the key generated by a password than in a randomly generated symmetric key. One well-known means for a hacker to attack password-encrypted files in a particular encryption system, therefore, is to compile a large lexicon of common passwords. The hacker converts each entry in the lexicon into a symmetric key in the same manner as the encryption system and then uses each such key in a brute-force attack against individual users using that system. This is known as a dictionary attack. One way to reduce vulnerability to dictionary attacks is to use salt. This is a random string of bits generated for each password individually and combined with the password in the generation of a symmetric key. The use of salt renders dictionary attacks more difficult, as it effectively forces an attacker to recompile the base lexicon for each target password. It should be understood nevertheless that salt is a limited countermeasure, and does not compensate for poor selection of passwords.

Passwords are, of course, also the most common way for users to authenticate when logging into accounts over the Internet. In this context, however, the password is

typically not used as an encryption key. Instead, the server to which the user is attempting to connect checks processed password information against a database entry for the requested account.

Message Integrity: Hash Functions and Message Authentication Codes

A critical problem that encryption alone does not solve is that of message integrity. When Bob sends a message to Alice encrypted using, for example, RC4, he may be reasonably well assured of the privacy of his communication if he uses the cipher correctly. When Alice receives his message, however, how does she know that Eve has not tampered with the message en route, by changing a few bits or words? Indeed, how does she even know that Bob is the one who sent the message? For this type of assurance, some additional cryptographic apparatus is required.

One of the workhorses of the cryptographic world is an algorithm known as a hash function, which is a form of cryptographic compression algorithm. It takes as input a message m of arbitrary length and produces a message digest of fixed length—typically on the order of a few hundred bits. This message digest is essentially a kind of fingerprint or checksum for the message m . Modifying even a single bit of m renders the checksum invalid. Thus, a message digest can detect message transmission errors. As a cryptographic primitive, however, a hash function offers much stronger properties than the mere error detection afforded by a simple checksum. A well-designed hash function yields message digests that resist message modifications by sophisticated and powerful adversaries.

A good hash function has the property of collision resistance, which means that it is infeasible—even using massive computing power—to find two messages, m_1 and m_2 that have an identical message digest. (Since a hash function takes inputs of arbitrary length, but has a fixed-length output, a simple counting argument shows that message collisions do exist. They are just hard to find.) The property of collision resistance implies another, subtly different property called “preimage resistance.” Given a particular message m_1 , it is hard to find a second message m_2 with an identical message digest.

Message digests can serve effectively as uniquely identifying, compact digital tags for messages or documents. One application, for example, is integrity assurance for software. Suppose that Alice's company wants to ensure that every new computer sent to an employee is configured in exactly the right way and contains no unauthorized programs, Trojans, or viruses. The IT (information technology) department might apply a hash function f to the hard-drive contents of an exemplar machine, obtaining a 256-bit message digest, which they publish on the company intranet. To inspect a new machine and ensure that it is configured identically with the exemplar, a company employee can download its hard-drive contents onto a trusted computer, apply the hash function f , and check that the resulting message digest is the same as that published by the IT department.

The most common hash functions in use today are MD5 (message digest 5), developed by Rivest, and SHA-1

(secure hash algorithm), developed by NIST. Recently uncovered, serious weaknesses in these two hash functions, however, are prompting industry migration to such hash functions as SHA-256 (so called because its digest length is 256 bits), a successor to SHA-1.

Hash functions are unusual cryptographic algorithms in that they have no secret keys associated with them. Alice might think of appending a message digest z to her e-mail message m to Bob as a way of ensuring that Eve does not tamper with it. Eve, however, can simply swap in a new message m' of her choice, compute and append a new message digest z' , deceiving Bob into thinking that the message originates with Alice.

It is possible, however, to combine a hash function with a secret key in precisely this setting so as to prevent message tampering. In particular, a tool known as a message authentication code (MAC) provides message integrity in symmetric-key settings. A MAC is essentially a hash function applied to a message *with* a secret key; viewed another way, it is like a cryptographically keyed checksum. Making use of a shared secret key, Alice can append a MAC to her messages to Bob so as to enable Bob to be sure that Eve has not tampered with them. MACs can be combined with encryption to achieve message confidentiality and integrity simultaneously.

In practice, naïve ways of combining hash functions with secret keys to build MACs do not achieve the rigorous technical assurances desired for well-designed cryptographic systems. Instead, well-designed industry applications today generally use HMAC, an algorithm developed by Bellare, Canetti, and Krawczyk (1996), whose security is based on strong theoretical underpinnings.

More on the Security of Symmetric-Key Cryptography

As already explained, in the area of encryption, cryptologists know of a truly complete mathematical proof of security only for the one-time pad. For DES, 3-DES, AES, RC4, and kindred ciphers, cryptographers have no such security proofs. Strong proof for these ciphers is not possible at present; belief in their security, however, rests on fairly well-explored (if heuristic) mathematical foundations. The same lack of fundamental proof applies to other cryptographic algorithms, such as hash functions. In fact, as mentioned above, the most common hash functions in use today have been recently shown to contain design weaknesses.

Shortly after the publication of DES, two cryptologists—Eli Biham and Adi Shamir (1991)—developed a technique called “differential cryptanalysis.” Roughly speaking, differential cryptanalysis involves statistical analysis of a cipher based on the way particular bits change (or do not change) in output ciphertexts when bits in certain positions are flipped in input plaintexts. The technique of differential cryptanalysis helped to confirm the strength of DES and to inform the design of later ciphers. (Some time after the academic development of differential cryptanalysis, it was publicly revealed that the technique had already been familiar to the government intelligence community, and had indeed helped guide the design of DES.)

Subsequently developed cryptanalytic techniques have further enhanced the collection of tools available to the cryptanalyst, influencing new designs for cryptographic algorithms in the process.

In analyzing the security of a cipher or MAC, one might consider Eve as an inert eavesdropper, attempting to decipher or modify the messages sent between Alice to Bob by harvesting and analyzing the ciphertexts they exchange. In fact, cryptologists also consider a range of ways in which Eve might try to tamper with or otherwise influence what messages Alice and Bob exchange in the hope of learning additional information. For example, if Alice encrypts all of her e-mail, then Eve might send a note containing a petition to Alice, and ask Alice to forward it to her friends. If Alice sends the petition to Bob while Eve is eavesdropping, then Eve learns a ciphertext for which she herself has selected the corresponding plaintext. In other words, Eve is able to perform active experimentation on the cipher. If Alice and Bob use a cipher that is poorly designed, then Eve may be able to gain information about their key in this way, or about messages they have exchanged with one another. This type of attack is known as a chosen-plaintext attack. It is an example of one of the types of attack against which cryptographers must ensure that their cipher designs are resistant. Analogous attacks against MACs are possible.

Even if a cryptographic primitive like a cipher is well designed, it must still be used with great care. Consider another example. Suppose that Alice and Bob always use a strong block cipher such as AES with a random 128-bit key to encrypt their communications. They perform encryption simply by dividing their messages into blocks and encrypting each block individually under their key. But suppose further that Eve knows that Alice and Bob exchange stock tips, and that these regularly take the form of simple buy and sell orders. Eve might then pass some stock tips to Alice, such as “Buy ABC, Inc.” and “Sell DEF Corp.,” and suggest that these be forwarded to Bob. If Eve eavesdrops while these stock tips are forwarded, then she learns what the corresponding ciphertexts look like. Thus, if Alice later sends the message “Buy ABC, Inc.” to Bob, Eve will be able to recognize the ciphertext and identify the corresponding buy or sell order. In other words, even though Alice and Bob are using a very strong cipher, Eve will be able to identify (and effectively, to decrypt) any of a small set of target messages!

The way that Alice and Bob use a block cipher is known as a mode of operation. The naïve example I just described is known as electronic code book (ECB) mode, a form whose use is avoided today in part because of the problem I have just described. To prevent Eve from learning what particular ciphertexts look like, Alice may adopt a mode of operation that involves the introduction of random bits into the message. One popular mode of operation today is known as cipher block chaining (CBC) mode. In this system, Alice divides her plaintext into blocks and inserts some freshly generated random bits at the beginning to serve as the first block. Alice then uses a principle of “chaining,” in which the encryption of one block is affected by the encryption of the previous one, thereby causing the randomness in the first block to propagate through the ciphertext. Although the architectural

motivations behind this mode are somewhat complex, its basic impact on message privacy is easy to understand. The fact that Alice introduces randomness into her ciphertexts means that the same plaintext is not encrypted twice the same way, and thus that Eve cannot trick Alice so as to recognize the stock tips or other plaintexts that Alice encrypts. Other modes of encryption aim at formally achieving additional security aims like message authentication. In particular, they enable Alice and Bob to ensure that the origin of messages is legitimate, and that the messages do not include spurious insertions or modifications made by Eve.

PUBLIC-KEY CRYPTOGRAPHY

Many years of research have led to the widespread deployment of strong symmetric-key ciphers and MACs capable of supporting high communication speeds. One might be tempted to believe that the basic problem of private communications has been solved and that the science of cryptology has run its course. Even if a symmetric-key cipher, hash function, or MAC is unbreakable, however, there remains a fundamental problem. I have assumed in this discussion that Alice and Bob share knowledge of a secret key. The question is: How do they obtain this key to begin with?

If Alice and Bob can meet face to face, in the absence of the eavesdropper Eve, then they may generate their shared key by repeatedly flipping a coin, or Alice may simply hand Bob a key written on a piece of paper or stored on a floppy disk. What if Alice and Bob wish to communicate privately over the Internet, however, without ever meeting? Alternatively, what if a commercial site on the Web wishes to enable any customer, new or old, to submit an order and credit-card number securely from anywhere in the world? The administrator of the Web site cannot possibly hope to communicate keys in private to all customers before they log in. To simplify the formidable difficulties that secure key distribution can pose, cryptographers have devised a form of mathematical magic known as public-key encryption or cryptography (also known as asymmetric-key cryptography, in contrast to symmetric-key cryptography). Using public-key cryptography, Alice and Bob can send each other encrypted messages securely, even if they have never met, and even if Eve has eavesdropped on all of their communications!

In a public-key cryptosystem, Alice possesses not one, but two keys. The first is known as her public key. Alice makes this key known to everyone; she may publish it on her Web page, in Internet directories, or in any other public place. Her second, mathematically related key is known as a private key. Alice keeps this key secret. She does not divulge it to anyone else, even people with whom she wishes to communicate privately. Together, the public key and private key are referred to as a key pair. Bob sends a private message to Alice by performing a computation using her public key, and perhaps a private key of his own as well.

Public-key cryptography is a powerful tool—indeed, one whose feasibility may at first seem counterintuitive. Even if Eve knows Alice and Bob's public keys, it is possible for Alice and Bob to communicate privately using

public-key cryptography. Moreover, with public-key cryptography, not only Bob, but Carol or any other party can achieve private communication with Alice over a public communication medium like the Internet.

Public-key cryptography can serve, moreover, not simply for encryption, but also for data integrity. Alice can use her private key not only to decrypt messages that people send her, but also to create digital signatures on messages—encrypted or unencrypted—that she sends others. Using Alice's public key, anyone can check the correctness of a message to which she has applied a digital signature. As I explain below, when a message bears a correct digital signature from Alice, it carries a very high assurance that not a single bit was modified by any other party subsequent to Alice's creation of the message.

Diffie-Hellman Key Exchange

Public-key encryption was the brainchild of Ralph Merkle, who in 1974 conceived a plausible, but somewhat impractical initial scheme. The idea saw its first practical form in 1976 in a seminal paper by Whitfield Diffie and Martin Hellman entitled "New Directions in Cryptography." Diffie and Hellman proposed a system in which Alice can combine her private key with the public key of Bob, and vice versa, such that each of them obtains the same secret key. Eve cannot figure out this secret key, even with knowledge of the public keys of both Alice and Bob. This system has come to be known as Diffie-Hellman key exchange, abbreviated D-H.

D-H exploits a form of mathematics known as modular arithmetic. Modular arithmetic is a way of restricting the outcome of basic mathematical operations to a set of integers with an upper bound. It is familiar to many schoolchildren as "clock arithmetic." Consider a clock on military time, by which hours are measured only in the range from zero to twenty-three, with zero corresponding to midnight and twenty-three to 11 o'clock at night. In this system, an advance of 25 hours on 3 o'clock brings us not to 28 o'clock, for example, but full circle to 4 o'clock (because $25 + 3 = 28$ and $28 - 24 = 4$). Similarly, an advance of 55 hours on 1 o'clock brings us to 8 o'clock (because $55 + 1 = 56$ and $56 - (2 \times 24) = 8$). In this case, the number 24, an upper bound on operations involving the measurement of hours, is referred to as a modulus. When a calculation involving hours on a clock yields a large number, we subtract the number 24 until we obtain an integer between 0 and 23, a process known as modular reduction. This idea can be extended to moduli of different sizes. For example, in the modulus 10, the sum of 5 and 7 would not be 12, which is larger than 10, but 2, because modular reduction yields $12 - 10 = 2$. We say that an arithmetic operation is modular when modular reduction is applied to its result. For example, modular multiplication is simply ordinary multiplication followed by modular reduction. We write $\text{mod } p$ to denote reduction under modulus p . Thus, for example, it is easily seen that $3 \times 4 \text{ mod } 10 = 2$.

Diffie and Hellman proposed a public-key cryptosystem based on modular multiplication, or more precisely, on modular exponentiation—that is, the repeated application of modular multiplication. Their scheme depends for

its security on the use of a modulus that is a very large number. In the systems used today, the modulus is typically an integer that is 1024 bits in length—that is, a little more than 300 decimal digits. It is also generally prime, which is to say that apart from the number 1, it is not divisible by any smaller integers. There are some additional, technical restrictions on the form of the modulus that I shall not explore here.

The security of D-H is based on the following idea. Suppose that p is a large modulus and g is an integer less than p (again, with some additional technical restrictions). Suppose that Alice selects a random integer a , also less than p . She then computes the integer $y = g^a \bmod p$ and gives the integers p , g , and y to Eve. It is believed by cryptologists that with this information alone, it is infeasible for Eve to figure out the value a . The task of figuring out a is known as the discrete logarithm problem, one that has been the subject of many years of study by mathematicians and cryptographers. Although the security of D-H is not directly based on the discrete logarithm problem, it is very closely related.

In D-H, the values p and g are standard, public values. They may be conveyed in some widely distributed piece of software, such as a browser. Alice selects a random integer a less than p as her private key and computes $y_{\text{Alice}} = g^a \bmod p$ as her public key—that is, the key that she publishes. Bob similarly selects a random integer b , also less than p , as his own private key, and computes $y_{\text{Bob}} = g^b \bmod p$ as his public key. Using her private key a , Alice can take the public key y_{Bob} and compute a value $k = (y_{\text{Bob}})^a \bmod p$. Bob, similarly, can compute exactly the same value k using y_{Alice} in combination with his own private key b . In particular, it is also the case that $k = (y_{\text{Alice}})^b \bmod p$ (thanks to the commutative properties of modular exponentiation). Eve, however, cannot figure out the secret k . This, at least, is the belief of cryptologists, based on the idea that Eve knows neither of the private keys a and b and on the difficulty of the discrete logarithm problem. Thus, if Alice and Bob use the secret k as the basis for private communication using a symmetric-key cipher like AES, Eve will be unable to eavesdrop successfully on their communications. This is a capsule summary of the idea behind the Diffie-Hellman cryptosystem. There are other details involved in making D-H a secure, workable

system, which I gloss over in this description. I also note in passing that an attractive feature of D-H is the fact that variants may be implemented over algebraic structures known as elliptic curves. This results in more compact key lengths and faster running times.

D-H is used, among other places, in some versions of PGP (pretty good privacy), a popular piece of encryption software used to secure Internet communications such as e-mail, and available as freeware in some versions.

The RSA Cryptosystem

A year after the publication of Diffie and Hellman's key exchange system, three faculty members at MIT proposed a new public-key cryptosystem. This cryptosystem is called RSA after its three inventors, Ronald Rivest, Adi Shamir, and Leonard Adleman. RSA is now the most widely deployed cryptosystem in the world (RSA Laboratories 2007).

Use of the RSA cryptosystem for encryption is very similar to the use of D-H. One superficial difference is that in the RSA cryptosystem, Bob can send an encrypted message to Alice without having a public key of his own. In particular, Bob can encrypt a message directly under Alice's public key in such a way that Alice can decrypt the ciphertext using her private key. Figure 2 diagrams this operation of RSA and similar public-key encryption schemes. (Much the same functionality can be achieved with D-H by having Bob generate a temporary key pair on the fly and using this as the basis for encryption of a message for Alice.)

There are two rather more important differences between the two cryptosystems. The first lies in the speed of their respective operations. In RSA, encryption is a very fast operation; it generally requires less computational effort than a D-H key exchange. Decryption, however, is several times slower for RSA than for key exchange in D-H. Another important difference between the two is a feature present in RSA. RSA can also be used to perform digital signing, an operation not covered in this chapter, but of central importance in cryptography. Digital signing achieves the goal of authenticating messages—that is, proving their origin, rather than concealing their contents.

Figure 2: Public-key encryption (e.g., RSA). Alice generates for herself a private key SK_A and corresponding public key PK_A . Suppose then that Bob wishes to transmit plaintext message m securely to Alice over a channel subject to eavesdropping. Bob encrypts m under public key PK_A to obtain ciphertext c , which he transmits to Alice. Eavesdropper Eve learns the ciphertext c and may also learn PK_A , as it is a public value. If the public-key encryption algorithm is well constructed and properly used, however, Eve should be unable to learn m .

The RSA system uses modular arithmetic, the same type of mathematical basis as for Diffie-Hellman key exchange. In D-H, the modulus is a published value that may be used by any party to construct his or her key pair. In RSA, however, every party uses a different modulus, published as part of his or her public key. Thus, if Bob wishes to encrypt a message for Alice, he uses a modulus N_{Alice} unique to the public key of Alice; if he wants to encrypt a message for Carol, he uses a different modulus, N_{Carol} . The reason for the use of different moduli is the fact that the value of the modulus in the RSA cryptosystem relates directly to that of the private key.

A modulus N in the RSA cryptosystem has a special form. It is the product of two large prime integers, generally denoted by p and q . In other words, $N = p \times q$. The pair of primes p and q are treated as private values in the RSA cryptosystem; they are used to compute the private key for the modulus N . Thus, the security of RSA is related very closely to the difficulty of determining the secret primes p and q given knowledge of the modulus N . This is known as the problem of factoring and is believed to be extremely difficult when p and q are large. In typical systems today, p and q are chosen to be primes of about 512 bits in length, so that N is an integer of about 1024 bits, the same length as generally selected for a Diffie-Hellman modulus. Factoring is the only effective method known for attacking RSA when the cryptosystem is used properly.

Among its many other uses, the RSA cryptosystem (along with RC4) is used as the basis for SSL, the encryption system in most Web browsers today, and also in some versions of PGP software.

More Technical Detail on RSA

I now describe in more mathematical detail how the RSA cryptosystem works. Unable as we are to delve further into the underlying mathematics, I provide only prescriptive formulae, without explaining the rationale behind them. For further information, the reader is directed to a good textbook (e.g., Menezes, van Oorschot, and Vanstone 2001).

To compute her public key, Alice selects two random primes, p_{Alice} and q_{Alice} , both of roughly equal length in bits (e.g., 512 bits long). The product

$$N_{\text{Alice}} = p_{\text{Alice}} \times q_{\text{Alice}}$$

is the modulus used by Alice in her public key. She also selects a small odd integer e_{Alice} ; generally, this value is more or less standardized in a given system, the integer 65535 being a common choice. An additional restriction on e_{Alice} is that it must not have a factor in common with $p_{\text{Alice}} - 1$ or $q_{\text{Alice}} - 1$, a criterion considered in the selection of primes. Together, the pair of values $(e_{\text{Alice}}, N_{\text{Alice}})$ constitutes Alice's public key. Her private key is computed as follows. Let $\Phi(N_{\text{Alice}}) = (p_{\text{Alice}} - 1) \times (q_{\text{Alice}} - 1)$. Alice computes her private key, generally denoted by d_{Alice} , in such a way that $e_{\text{Alice}} d_{\text{Alice}} = 1 \pmod{\Phi(N_{\text{Alice}})}$. The bit-length of the private key d_{Alice} here is typically quite close to that of N_{Alice} .

A message in the RSA cryptosystem consists of a positive integer m less than N_{Alice} . To encrypt m , Bob computes the ciphertext

$$c = m^{e_{\text{Alice}}} \pmod{N_{\text{Alice}}}.$$

As a technical restriction required to achieve good security, the plaintext m is formatted so as to be about equal in length to the modulus, resulting in a ciphertext that is similarly so. To decrypt the ciphertext, Alice applies her private key and computes

$$m = c^{d_{\text{Alice}}} \pmod{N_{\text{Alice}}}.$$

An Example

Let us consider a small example to provide some flavor of how the RSA cryptosystem works. For illustrative purposes, we consider integers much smaller than those needed for true, secure use of RSA. Suppose that p_{Alice} and q_{Alice} are 5 and 11, respectively. Then $N_{\text{Alice}} = 5 \times 11 = 55$. Observe that $e_{\text{Alice}} = 3$ does not divide $p_{\text{Alice}} - 1$ or $q_{\text{Alice}} - 1$. Thus, Alice can use $(e_{\text{Alice}}, N_{\text{Alice}}) = (3, 55)$ as her public key. A valid private key for Alice is $d_{\text{Alice}} = 27$, because $\Phi(N_{\text{Alice}}) = (p_{\text{Alice}} - 1) \times (q_{\text{Alice}} - 1) = (5 - 1) \times (11 - 1) = 40$, and $e_{\text{Alice}} \times 27 = 81 = 1 \pmod{40}$.

To encrypt the message $m = 7$, Bob computes the ciphertext $c = 7^3 \pmod{55} = 343 \pmod{55} = 13$. Alice decrypts the ciphertext $c = 13$ by computing $13^{27} \pmod{55}$. Using a pocket calculator, the reader can easily verify that the result of this decryption operation is indeed the original plaintext $m = 7$.

The security of RSA requires some special, technical restrictions on the value of m . In fact, as the RSA cryptosystem is generally used, the message m is itself the key for a symmetric-key cryptosystem such as AES, and is specially formatted prior to encryption. Public-key cryptosystems are generally used in conjunction with symmetric-key cryptosystems, as discussed below.

With a 1024-bit RSA modulus, a Pentium Celeron processor running at about 2 GHz can perform roughly 150 RSA decryption operations per second, and about 2250 encryption operations per second under the public exponent $e = 65535$. (These speeds, of course, can vary enormously depending on the particular software implementation and system configuration.)

As explained above, the security of the RSA cryptosystem is closely related to the difficulty of factoring the product of two large primes. Security guidelines for RSA thus depend on advances in the factoring problem made by researchers, as well as the cost and availability of computing power to a potential attacker. According to guidelines issued in April 2005 by NIST, 1024-bit RSA moduli may be used for most data-security applications through 2009. For more sensitive data, or for security needs beyond that date, a 2048-bit RSA modulus is recommended instead. Although there is substantial debate and uncertainty among cryptographers as to the exact ongoing security level afforded by RSA, there is general agreement as to the rough accuracy of these predictive guidelines. To avoid a common misconception, it should be emphasized that the mathematical basis for the RSA cryptosystem means that the recommended modulus lengths, and thus the public

and private keys, are substantially longer than the 128- to 256-bit key lengths prescribed for symmetric-key ciphers.

How Public-Key Encryption Is Used

Encryption of a large quantity of data is generally much slower using a public-key cryptosystem than using a symmetric-key cipher. On the other hand, public-key encryption offers an elegant approach to the problem of distributing keys that is unavailable in symmetric-key ciphers. It is common in practice, therefore, to combine the two types of encryption systems in order to obtain the best properties of both. This is achieved by use of a simple principle known as enveloping. Enveloping involves use of a public-key cryptosystem such as RSA as a vehicle for transporting a secret key, which is itself then used for encryption with a symmetric-key cipher. To send a megabyte-long file to Alice, for example, Bob might select a random 128-bit RC4 key k and encrypt the file under k . He would then send this ciphertext of the file to Alice, along with an RSA encryption of k under Alice's public key. In effect, enveloping is a way of making a public-key cryptosystem faster. Enveloping yields much the same data flows as in Figure 2. The only difference is that a symmetric key k is encrypted rather than an ordinary plaintext m ; in addition to the public-key ciphertext c , Bob also transmits a symmetric-key ciphertext c' , namely the message m encrypted under k using a symmetric-key cipher.

As with symmetric-key ciphers, cryptologists aim to design public-key cryptosystems to withstand a wide range of possible attacks, involving some very strong ones in which, for example, Eve can persuade Alice to decrypt a range of ciphertexts that Eve herself selects. Like symmetric-key block ciphers, when used in a naïve manner, RSA has a limitation in that encryption of the same plaintext always yields the same ciphertext; it also has the additional weakness of leaking some bits of a plaintext. Prior to encryption under RSA, therefore, it is common practice to subject a message to a special type of formatting that involves the addition of random bits. Loosely speaking, this incorporation of randomness serves much the same purpose as in the case of cipher-block chaining for symmetric-key block ciphers, as described above. Other aspects of the formatting process permit the RSA cryptosystem to withstand other forms of attack, and to do so with guarantees that are subject to rigorous mathematical justification.

Most public-key encryption systems have an additional advantage over symmetric-key systems, in that they permit a flexible approach to distributed storage of the private key, known as secret sharing. This is a way of mathematically splitting a private key into a number of elements known as shares. To achieve a decryption operation, each of these shares may be applied individually to a ciphertext, without the need to assemble the shares themselves in a single place. Thus, a cryptosystem can be set up so that compromise of any one share does not expose the full decryption key itself. For example, Alice can divide her private key into, say, three shares, keeping one for herself and giving one each to her friends Bob and Carol. To decrypt a ciphertext, Alice can ask Bob and Carol to apply their shares and to send her the result. Alice can then complete the decryption with her own share, without Bob or Carol

seeing the resulting plaintext. If an attacker breaks into Alice's computer and obtains her share, the attacker will still be unable to decrypt ciphertexts directed to Alice (without also obtaining the assistance of Bob and Carol). The system can even be set up so that decryption is possible given particular sets of shares. Thus, for example, Alice might be able to achieve decryption of her ciphertexts even if Bob or Carol is on vacation.

Despite its great flexibility, public-key cryptography does not directly address all the challenges of key distribution. For example, we have said that Alice can safely disseminate her public key as widely as she likes, publishing it in Internet directories and so forth. But when Bob obtains a copy of Alice's public key, how does he really know it belongs to Alice, and is not, for example, a spurious key published by Eve to entrap him? To solve problems of this kind, we appeal to a public-key infrastructure (PKI), as explained in detail in, for example, Perlman (2006). Another issue worth mentioning—and a pitfall for many system designers—is the problem of finding an appropriate source of randomness for generating keys. Good generation of random bits is the cornerstone of cryptographic security and requires careful attention.

DIGITAL SIGNATURES

Public-key cryptography can be used not only for encryption, but also for message integrity. A digital signature is the public-key analog of a message authentication code. In fact, the RSA cryptosystem itself can be used to perform message signing, and is the most commonly used algorithm for that purpose. To apply a digital signature to a message m , Alice executes an RSA operation using her private key SK_A . That is to say that (setting aside low-level differences) Alice performs a decryption operation on m —i.e., exponentiation by d_{Alice} —to produce a digital signature Σ_m . Anyone with access to Alice's public key PK_A can verify the signature Σ_m on m . The verification procedure is essentially like that of encryption—that is, it involves exponentiation by e_{Alice} .

Of course, the need to apply digital signatures to long messages is as common as that of encrypting long messages. Digital signing, therefore, requires a procedure analogous to enveloping so that a single application of the RSA algorithm suffices to sign a long message. In the case of digital signatures, messages are compressed prior to signing by means of a hash function. This is to say that in generating Σ_m , Alice does not apply the RSA algorithm directly to m , but instead to a specially processed message digest m .

A message digest is in fact padded prior to signing. *Padding* is a randomized transform that meets the bit-length requirements of the RSA algorithm and also provides important security assurances. The optimal asymmetric encryption padding (OAEP) of Bellare and Rogaway (1994) is the most common form of padding in use with RSA today.

Certificates

As explained above, public-key encryption addresses the problem of key management—that is, the distribution of secret keys between communicating parties. Simply by

exchanging their respective public keys, PK_A and PK_B , Alice and Bob can communicate privately without ever meeting in secret. But even public-key cryptography leaves an unresolved problem. When Bob receives a public key from Alice—via e-mail, for instance—how does he know that it is authentic? How does he know, for example, that Eve has not impersonated Alice and sent him her own public key PK_E , so that she can decrypt messages that Bob sends to Alice?

Digital signatures support a tool for secure distribution of public keys. Suppose that Alice and Bob both possess the public key PK_T of a mutually trusted third party, Trent. Trent can help Alice and Bob exchange public keys by certifying their correctness. Suppose that Trent creates a digital signature $\Sigma_{T,A}$, on a message that includes Alice's key PK_A as well as her name, "Alice." If Bob receives PK_A along with Trent's signature $\Sigma_{T,A}$, then by verifying the correctness of $\Sigma_{T,A}$, he can leverage his trust in Trent to assure himself that he has indeed received a correct key for Alice. The digital signature $\Sigma_{T,A}$, which binds Alice's key to her name, is known as a *certificate*.

Certificates are very flexible. They can support diverse sets of trust relationships. To assure Bob that PK_T itself is valid, for example, Trent might obtain a certificate binding PK_T to the name "Trent" from a trusted organization—for example, a town government. To provide further assurance, the town government might have its own certificate digitally signed by a state government, and so forth. A sequence of certificates of this kind is called a "certificate chain." Bob's trust in the certificate at the bottom of chain—Alice's, in this example—relies on Bob's trust of the public key (or certificate) at the top of the chain. Bob's trust in the chain, therefore, depends on his preexisting trust in the certificate at the top of the chain. Thus, a network of certificates and public keys relies on a small set of universally trusted public keys against which certificate chains may be anchored. These public keys are called "root keys." A system of public-key cryptography with supporting certificates is called a "public-key infrastructure" (PKI).

Certificates play an important role in Web browser security. Web sites that implement SSL present their public keys to the browsers of visiting users in the form of certificates. (By clicking on the lock appearing in the browser during an SSL session, you can obtain information about the certificate, including the name of the entity that owns it, and various cryptographic characteristics, like the associated RSA-key length.) Browser certificates bind public keys to the identities (domain names) of the sites that possess them. To permit the verification of SSL certificates, browsers come with preinstalled set of root keys.

CONCLUSION

Encryption algorithms, hash functions, message authentication codes, and digital signatures, as described above, are the most commonly deployed cryptographic primitives, but are just the tip of the iceberg. Just a few other notable cryptographic tools are:

Challenge-response authentication—A MAC or digital signature can serve not just to authenticate a message, but also to authenticate a device. For example, many automobile ignition keys today contain tiny wireless

devices that perform a digital authentication protocol with a reader inside the vehicle. (This procedure serves as a countermeasure to hot-wiring and to undesirable copying of keys.) The reader shares a secret key k with the ignition key. When the ignition key is placed in the key slot by the steering column, the reader transmits a random value c —referred to as a challenge—to the ignition key. The ignition key computes a MAC z on the challenge c , and returns z to the reader. Only if the MAC is correct does the automobile start. Many other wireless devices, like payment tokens, use similar protocols, and some devices use public-key variants involving digital signatures.

Identity-based encryption (IBE)—IBE is a form of encryption developed by Boneh and Franklin in 2001 (Boneh and Franklin 2003). It permits the transmission of encrypted messages without the need for a sender to look up the public key or associated certificate of a receiver. In this system, the name of the receiver, or associated information like her e-mail address, is in fact her public key. (The system does require distribution of a master key, however.) The mathematics underlying IBE is quite elegant and useful for minimizing communication in other cryptographic applications.

Digital rights management (DRM)—Designers of systems to restrict unauthorized dissemination of media have pressed a range of cryptographic tools into service. One example is broadcast encryption, a set of techniques that permits content to be encrypted for a dynamically changing set of entities. For example, cable television providers wish to encrypt their broadcasts so as to prevent pirating of their content. They would like valid set-top boxes to be able to decrypt content, but would also like to be able to render content inaccessible to consumers whose subscriptions have lapsed or to pirated set-top boxes. Sophisticated schemes for distributing cryptographic keys can support the dynamic access privileges required in such an environment. In addition, some broadcast encryption schemes support a complementary process of traitor tracing, namely the ability on examining a set-top box to determine which keys it contains and thereby implicate the sets of valid set-top boxes involved in the creation of pirate boxes.

At the frontiers of cryptology are ideas beyond the traditional conceptual and physical boundaries of computing systems. In some cases, for instance, a clever attacker can extract a secret key from a device by observing side information, like computing time and power consumption. The field of side-channel analysis involves the development of countermeasures to these devious attacks. Some researchers are casting much farther afield, and considering technologies that may play a role in cryptology in decades to come, such as computers and networks that operate on quantum-mechanical principles.

GLOSSARY

AES: The advanced encryption standard, a symmetric-key cipher known as Rijndael, serving as a successor to DES.

Asymmetric: In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption

key. These keys are respectively referred to as public and private. RSA and D-H are examples of asymmetric systems. *Asymmetric* is synonymous with *public-key*.

Certificate: A digitally signed public key and associated information; a certificate generally creates an authenticated binding of a key to an owner.

Ciphertext: The data conveying an encrypted message.

Cryptanalysis: The science of analyzing weaknesses in cryptographic systems.

Cryptography: The science of constructing mathematical systems for securing data.

Cryptology: The combination of the complementary sciences of cryptography and cryptanalysis.

Cryptosystem: A complete system of encryption and decryption, typically used to describe a public-key cryptographic system.

Decryption: The process of obtaining a readable message (a *plaintext*) from an encrypted transformation of the message (a *ciphertext*).

DES: The data encryption standard, an existing form of symmetric cipher in wide use today, often in a strengthened variant known as triple DES.

Diffie-Hellman (D-H): A public-key cryptosystem used to exchange a secret (symmetric) key.

Digital Signature: Information appended to a message that ensures its integrity and authenticity; generally used to describe information derived from a public-key cryptosystem.

Encryption: The process of rendering a message (a *plaintext*) into a data string (a *ciphertext*) with the aim of transmitting it privately in a potentially hostile environment.

Enveloping: A method for using a symmetric-key cipher in combination with a public-key cryptosystem to exploit simultaneously the advantages of the two respective systems.

Hash Function: A cryptographic algorithm that compresses a message of arbitrary length into a fixed-length *message digest*.

HMAC: A commonly used MAC scheme.

Key: A short data string parameterizing the operations within a cipher or cryptosystem, and whose distribution determines relationships of privacy and integrity among communicating parties.

Key Pair: The combination of a public and private key.

Message Authentication Code (MAC): Information appended to a message that ensures its integrity and authenticity; generally used to describe information derived from a symmetric-key cryptographic algorithm.

Message Digest: The output yielded by a hash function; a message digest serves as a cryptographic checksum or fingerprint on a digital message.

Plaintext: A message in readable form, prior to encryption or subsequent to successful decryption.

Private Key: In an asymmetric or public-key cryptosystem, the key that a communicating party holds privately and uses for decryption or completion of a key exchange.

Public Key: In an asymmetric or public-key cryptosystem, the key that a communicating party disseminates publicly.

Public Key: In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and D-H are examples of public-key systems. *Public key* is synonymous with *asymmetric*.

RC4: A symmetric-key cipher of the type known as a stream cipher. Used widely in the SSL (secure sockets layer) protocol.

RSA: A public-key cryptosystem in very wide use today, as in the SSL (secure sockets layer) protocol. RSA can also be used to create and verify digital signatures.

Symmetric: A type of cryptographic system in which communicating parties use shared secret keys. The term is also used to refer to the keys used in such a system.

FURTHER READING

Two broad and accessible introductory books on the field of cryptology are *Applied Cryptography*, by Bruce Schneier (2002), and the online compendium *Frequently Asked Questions about Today's Cryptography* (RSA Laboratories 2006). A more detailed technical treatment of cryptographic techniques and concepts, along with an extensive bibliography, may be found in the excellent *Handbook of Applied Cryptography*, by Alfred J. Menezes, Paul C. van Oorschot, and Scott A. Vanstone (2001). Detailed information on the AES algorithm (Rijndael) is available in *The Design of Rijndael*, by Joan Daeman and Vincent Rijmen (2002).

Readers interested in the practical application of cryptography in real-world systems may wish to consult

Network Security: Private Communication in a Public World, by Charlie Kaufman, Radia Perlman, and Mike Speciner (2002) and *Cryptography and Network Security: Principles and Practice*, by William Stallings (2002). For a more comprehensive view of security engineering, an excellent work is Ross Anderson's *Security Engineering: A Guide to Building Dependable Distributed Systems* (2001). Of similar interest is Bruce Schneier's *Secrets and Lies* (2004), which offers some caveats regarding the limitations of cryptography and other security tools.

A good introductory textbook of a more academic flavor is *Cryptography: Theory and Practice*, by Douglas Stinson (2005). For information on the foundational mathematics and theory of cryptology, an important work is *Foundations of Cryptography* by Oded Goldreich; this evolving series now includes two volumes: *Foundations of Cryptography: Basic Tools* (2000) and *Foundations of Cryptography: Basic Applications* (2004). For a historical overview of cryptology, the classic text is *The Codebreakers*, by David Kahn (1996). More up-to-date, although less exhaustive, is *The Science of Secrecy from Ancient Egypt to Quantum Cryptography*, by Simon Singh (2000).

The use and export of products containing strong cryptographic algorithms were at one time strongly restricted by regulations of the U.S. government and other nations. The U.S. government dramatically relaxed its restrictions in 2000, however, as did many other nations at around the same time. Some countries, such as China, still retain strong regulations around both domestic use and import and export of cryptographically enabled products. While regulations treating the use of cryptography are in frequent flux, readers may refer to Electronic Privacy Information Center (2006) for historical and current information on this topic.

Many cryptologists are members of the International Association for Cryptologic Research (IACR), whose home page (IACR 2006) lists publications and conferences devoted to advanced research in cryptography and cryptanalysis.

INTRODUCTION

An important requirement of any system is to protect its data and resources against unauthorized disclosure (secrecy or confidentiality) and unauthorized or improper modifications (integrity), while at the same time ensuring their availability to legitimate users (no denial-of-service or availability) (Samarati and De Capitani di Vimercati 2001). The problem of ensuring protection has existed since information has been managed. However, as technology advances and information management systems become more and more powerful, the problem of enforcing information security also becomes more critical. The development of information technology in the past few years has led to the widespread use of computer systems to store and manipulate information and has greatly increased the availability, the processing power, and the storage power of information systems. However, it has also posed new serious security threats and has increased the potential damage that violations may cause. More than ever today, organizations depend on the information they manage. A violation to the security of the information may jeopardize the whole system and cause serious damages. Hospitals, banks, public administrations, private organizations—all of them depend on the accuracy, availability, and confidentiality of the information they manage. Just imagine what could happen, for example, if an organization's data were improperly modified, were not available to the legitimate users because of a violation blocking access to the resources, or were disclosed to the public. For instance, imagine the damage that could be caused by the improper modification of a prescription for a medication.

A fundamental component in enforcing protection is represented by the access control service whose task is to control every access to a system and its resources and ensure that all and only authorized accesses can take place. Access control usually requires authentication (i.e., the process of certifying the identity of one party to another) as a prerequisite. In general, when considering an access control system, it is necessary to make a distinction among access control policies, access control models, and access control mechanisms. A policy defines the (high-level) rules, expressed using an adequate language,

according to which access control must be regulated. A model provides a formal representation of the access control security policy and its working. The formalization allows the proof of properties of the security provided by the access control system being designed. A mechanism defines the low-level (software and hardware) functions that implement the controls imposed by the policy and formally stated in the model. Access control policies may be grouped into three main classes: discretionary, mandatory, and role-based (described in the section on "Access Control Policies").

In the remainder of this chapter, we start with a brief overview of the basic approaches to access control policies, and continue with a discussion of the main desiderata for an access control system. We then survey the access control services provided by some of the most popular operating systems, database management systems, and network solutions. Although clearly their characteristics will vary from one class to the other as their focus is different (e.g., database management systems focus on the data and rely on the operating systems for low-level support), we will comment on how they accommodate (or do not accommodate) the features introduced in the section on desiderata. Also, while covering a feature in some way, some systems take unclear solutions that may have side effects in terms of security or applicability, aspects that should be taken into account when using the systems. We therefore present an overview of different access control solutions, outlining their strengths and limitations. This can serve as an interesting reference for readers involved in access control development and access control specifications. It is, however, important to highlight that no solution is more secure in absolute terms; each solution has to be evaluated depending on the specific context and protection requirements that need to be enforced.

ACCESS CONTROL POLICIES

Access control policies can be grouped into three main classes: discretionary, mandatory, and role-based (Castano et al. 1995). We now briefly describe the main characteristics of these policies.

	Invoice	Order	Program
Ann	Own, Read, Write	Read	Read, Execute
Bob	Read, Write		Execute
Carol		Own, Read, Write	

Figure 1: Example of an access matrix

The discretionary access control (DAC) policies control access based on users' identities and on a set of rules, called "authorizations," explicitly stating which subjects can execute which actions on which resources. Early approaches to authorization specifications use authorization triples (s, o, a) stating that user s can execute action a on object o . One of the first models that provided a framework for describing DAC policies is the access matrix model (Lampson 1974). In this model, the state of the system is represented through a triple (S, O, A) , where S is the set of subjects, O is the set of objects, and A is a matrix with a row for each subject $s \in S$ and a column for each object $o \in O$. Each entry $A[s, o]$ contains the set of actions that subject s is allowed to perform over object o . Figure 1 illustrates an example of access matrix. The access control matrix is usually not very suitable for direct implementation because it is likely to be sparse. For this reason, the access matrix is typically implemented according to the following three mechanisms.

- *Authorization table.* Nonempty entries in A are stored in a table with three columns: user, action, and object.
- *Capabilities.* Capabilities correspond to rows of the access matrix. Each subject is associated with a list of objects, together with the set of actions she can perform on each of them.
- *Access control lists (ACLs).* ACLs correspond to columns of the access matrix. Each object is associated with a list of subjects, together with the set of actions they can perform on the object.

Figure 2 shows the authorization table, capabilities, and access control lists, respectively, corresponding to the access matrix in Figure 1. Note, however, that recent access control approaches support authorizations more complex than the simple authorization triple (s, o, a) . These approaches allow conditions to be associated with authorizations to restrict their validity, and support the concept of user groups, which greatly simplifies management of authorizations, since a single authorization granted to a group can be enjoyed by all its members. Also, since there will be many cases in which exceptions (i.e., authorizations applicable to all members of a group but few) will need to be supported, modern access control solutions support both positive and negative authorizations (Samarati and De Capitani di Vimercati 2001).

The main problem of DAC policies is that they ignore the distinction between a user (a human entity interacting with the system) and a subject (a process generated by a user). This implies that all requests submitted by a process running on behalf of some user are evaluated

against the authorizations of the user. This aspect makes discretionary policies vulnerable to Trojan horses. A Trojan horse is a computer program with an apparently useful function, which contains a piece of malicious code. This piece of code is hidden to the user and exploits the authorizations of the invoking user to make actions it would not be allowed to. As an example, consider two users, namely Alice and Bob, and suppose that Alice is the owner of a file, namely file A, that contains highly sensitive data and such that no users other than Alice are authorized to access the file. Bob wants to read the content of such a file and implements a useful utility program. In this utility program, Bob embeds a hidden function that reads file A and copies the contents into a file, namely file B. File B has an ACL associated with it that allows processes executing on Alice's behalf to write to it, while allowing Bob's processes to read it. When Alice executes the utility program, it assumes her identity and thus her access rights to file A. The utility program then copies the contents of file A to file B. This copying takes place within the constraints of the DAC policy, and Alice is unaware of what is happening.

The problem of Trojan horses is solved by mandatory access control (MAC) policies. In general, these policies control access based on mandated regulations determined by a central authority. The most common form of MAC policies is the multilevel security policy, based on classifications associated with subjects and objects. An access class is usually composed of two elements: a security level and a set of categories. Security levels are an ordered set of elements, while categories are an unordered set of elements that define the area of competence of users and data. Consequently, access classes form a partially ordered set, in which the dominance relationship, which defines the partial order among access classes, is defined as follows: class c_1 dominates class c_2 if the security level of c_1 is greater than or equal to the security level of c_2 and the set of categories in c_2 is a subset of or is equal to the set of categories in c_1 . The set of access classes together with the dominance relationship form a lattice.

For instance, consider a system with two security levels, Top Secret (TS) and Secret (S), where $TS > S$, and two categories, Economic and Financial. The corresponding lattice has eight access classes, as illustrated in Figure 3. The top element of the lattice is $\langle TS, \{Economic, Financial\} \rangle$, while the bottom element is $\langle S, \{\} \rangle$. Access requests are granted or denied on the basis of the relationship between the classes of the requesting subjects and of the requested objects. In particular, there are two kinds of multilevel mandatory security policy: secrecy-based (Bell and LaPadula 1973) and integrity-based (Biba 1977).

User	Action	Object
Ann	Own	Invoice
Ann	Read	Invoice
Ann	Write	Invoice
Ann	Read	Order
Ann	Read	Program
Ann	Execute	Program
Bob	Read	Invoice
Bob	Write	Invoice
Bob	Execute	Program
Carol	Own	Order
Carol	Read	Order
Carol	Write	Order

(a)

(b)

(c)

Figure 2: Authorization table (a), capabilities (b), and access control lists (c) corresponding to the access matrix in Figure 1

The goal of a secrecy mandatory policy is to protect data confidentiality. The security level of the access class associated with an object reflects the sensitivity of the information it contains. The security level of the access class associated with a subject, called “clearance,” reflects the degree of trust placed in the subject not to disclose

sensitive information to users not cleared to see it. This policy prevents flows of information from high- to low-level access classes by applying the no-read-up and no-write-down principles, first formulated by Bell and La Padula (1973). According to these two principles, a subject can read objects with access classes dominated by her

Figure 3: Example of a security lattice

classification and can write objects with access classes that dominate her classification. It is easy to see that the secrecy mandatory policy is robust against Trojan horse attacks. Consider the scenario previously described, and suppose that the system now implements a secrecy mandatory policy with two security levels, namely TS and S, with $TS > S$. For the sake of simplicity, we ignore the set of categories. Alice operates at level TS, and the security level associated with file A is TS. Bob operates at level S because he is not allowed to access sensitive data, and the security level associated with file B is S. As before, Bob's Trojan horse program is executed by Alice. Within the constraints of the mandatory policy, the utility program reads file A. However, when the Trojan horse tries to write the sensitive data into file B, this operation is not allowed because it violates the no-write-down principle.

The goal of an integrity mandatory policy is to protect data integrity. As for secrecy, each subject and object is associated with an integrity class. The integrity classes and the dominance relationship are defined as before. In this case, the integrity level of the integrity class associated with an object reflects the degree of trust placed on the information stored in the object and the potential damage that could derive from unauthorized modifications. The integrity level of the integrity class associated with a subject reflects instead the degree of trust placed in the subject to manipulate sensitive objects. This policy prevents flows of information from low- to high-level access classes by applying the no-read-down and no-write-up principles. According to these two principles, a subject can read objects with access classes that dominate her classification and can write objects with access classes dominated by her classification.

Role-based access control (RBAC) policies (Sandhu et al. 1996) are based on the observation that access privileges are usually assigned to users not on the basis of their identity, but depending on the organizational activities and responsibility that the users have in the considered organization. The central notion of RBAC is therefore that authorizations are associated with roles and users are assigned to appropriate roles. Roles are created for the various activities in the organization and users are assigned to roles according to their responsibilities (see Figure 4). This greatly simplifies the management of authorizations because the authorization specification task is partitioned into two subtasks: (1) assignment of roles to users, and (2) assignment of authorizations to roles.

In general, a user can play different roles on different occasions, and a role can be played by different users,

Figure 4: Role-based access control

possibly simultaneously. Sophisticated approaches for RBAC support the definition of relations between roles as well as between authorizations and roles and between users and roles. For instance, two roles can be defined as mutually exclusive; thus, the same user is not allowed to play both roles (separation of duties principle). RBAC also has other advantages. It can easily support the concept of least privilege, which requires the identification of the user's job functions, the definition of the minimum set of privileges required to perform those functions, and the restriction for the user to play only the role with which those privileges are associated, and nothing more. In real applications, users who can play different roles may need to perform common operations. For instance, some general operations can be executed by all employees. In this situation, it would be inefficient to specify these general operations for each role. A role hierarchy can be then exploited for authorization implication. Figure 5 illustrates an example of a role hierarchy, where each role is represented as a node and there is an arc between a specialized role and its generalization. Authorizations granted to roles can be propagated to their specializations (e.g., the secretary role can be allowed all authorizations granted to admin_staff). Authorization implication can also be enforced on role assignments, by allowing users to activate all generalizations of the roles assigned to them.

RBAC represents therefore a useful paradigm for many commercial and governmental organizations. The strong interest in RBAC is also visible in the standard arena. For instance, roles are part of the SQL:2003 standard for database management systems (see section on "Access Control in Database Management Systems").

Figure 5: Example of role hierarchy

DESIDERATA FOR AN ACCESS CONTROL SYSTEM

The definition of access control policies to be fed into the access control system is far from being a trivial process. One of the major difficulties lies in the interpretation of often complex and sometimes ambiguous, real-world security policies and in their translation in well-defined unambiguous rules enforceable by the computer system. Many real-world situations have complex policies, in which access decisions depend on the application of different rules coming, for example, from law practices, and organizational regulations. A security policy must capture all the different regulations to be enforced and, in addition, must consider all possible additional threats due to the use of computer systems. Given the complexity of the scenario, it is therefore important that the access control service provided by the computer system is expressive and flexible enough to accommodate all the different requirements that may need to be expressed, while at the same time it should be simple both in terms of use (so that specifications can be kept under control) and implementation (so to allow for its verification).

An access control system should include support for the following concepts/features.

- *Accountability and reliable input.* Access control must rely on a proper input. This simple principle is not always obeyed by systems, allowing access control rules to be evaluated on the basis of possibly unreliable information. This is, for example, the case of location-based access control restrictions, in which the access decision may depend on the IP from which a request originates, information that can be easily faked in a local network, thus fooling access control (allowing nonlegitimate users to acquire access despite the proper rule enforcement). This observation has been traditionally at the basis of requiring proper user authentication as a prerequisite for access control enforcement (Sandhu and Samarati 1997). Although more recent approaches may remove the assumption that every user is authenticated (e.g., credential-based access control), the assumption that the information on which access decision is taken must be correct continues to hold.
- *Support for fine- and coarse-specifications.* The access control system should allow rules to be referred to specific accesses, providing fine-grained reference to the subjects and objects in the system. However, fine-grained specifications should be supported, but not forced. In fact, requiring the specification of access rules with reference to every single user and object in the system would make the administrative task a heavy burden. Besides, groups of users and collections of objects often share the same access control requirements. The access control system should then provide support for authorizations specified for groups of users, groups of objects, and possibly even groups of actions (Jajodia et al. 2001). Also, in many organizational scenarios, access needs may be naturally associated with organizational activities; the access control system should then support authorizations reflecting organizational roles (Sandhu et al. 1996).
- *Conditional authorizations.* Protection requirements may need to depend on the evaluation of some conditions (Samarati and De Capitani di Vimercati 2001). Conditions can be in the simple form of system's predicates, such as the date or the location of an access (e.g., "Employee can access the system from 9 A.M. to 5 P.M."). Conditions can also make access dependent on the information being accessed (e.g., "Managers can read payroll data of the employees they manage.").
- *Least privilege.* The least privilege principle mandates that every subject (active entity operating in the system) should always operate with the least possible set of privileges needed to perform its task. Obedience of the least privilege principle requires both static (policy specification) and dynamic (policy enforcement) support from the access control system. At a static level, least privilege requires support of fine-grained authorizations, granting to each specific subject only those specific accesses it needs. At a dynamic level, least privilege requires restricting processes to operate within a confined set of privileges. Least privilege is partially supported within the context of RBAC (see above). Authorizations granted to a role apply only when the role is active for a user (i.e., when needed to perform the tasks associated with the role) (Gong 1999). Hence, users authorized for powerful roles do not need to exercise them until those privileges are actually required. This minimizes the danger of damages due to inadvertent errors or to intruders masquerading as legitimate users. Least privilege also requires the access control system to discriminate between different processes, even if executed by the same user—for example, by supporting authorizations referred to programs or applicable only within the execution of specific programs. A robust implementation of the least privilege principle is needed in order to avoid the threat coming from privilege escalation, in which a user starts from a limited authorized access and obtains greater privileges, typically exploiting a vulnerability unavailable to outside users.
- *Separation of duty.* Separation of duty refers to the principle that no user should be given enough privilege to misuse the system on her own (Sandhu 1990). While separation of duty is better classified as a policy specification constraint (i.e., a guideline to be followed by those in charge of specifying access control rules), support of separation of duty requires the security system to be expressive and flexible enough to enforce the constraints. At a minimum, fine-grained specifications and least privilege should be supported; history-based authorizations, making one's ability to access a system dependent on previously executed accesses, are also a convenient means to support separation of duty.
- *Multiple policies and exceptions.* Traditionally, discretionary policies have been seen as distinguished into two classes: closed and open (Samarati and De Capitani di Vimercati 2001). In the most popular closed policy, only accesses to be authorized are specified; each request is controlled against the authorizations and allowed only if an authorization exists for it. By contrast, in the open policy, (negative) authorizations specify the accesses that should not be allowed. By default, all access requests

for which no negative authorization is specified are allowed.

- *Policy combination and conflict-resolution.* If multiple modules (e.g., for different authorities or different domains) exist for the specification of access control rules, the access control system should provide a means for users to specify how the different modules should interact—for example, if their union (maximum privilege) or their intersection (minimum privilege) should be considered. Also, when both permissions and denials can be specified, the problem naturally arises of how to deal with incompleteness (existence of accesses for which no rule is specified) and inconsistency (existence of accesses for which both a denial and a permission are specified). Dealing with incompleteness—requiring the authorizations to be complete would be very impractical—requires support of a default policy either imposed by the system or specified by the users. Dealing with inconsistencies requires support of conflict-resolution policies. Different conflict-resolution approaches can be taken, such as the simple denials take precedence (in the case of doubt, access is denied) or most specific criteria that make the authorization referred to the more specific element (e.g., a user is more specific than a group, and a file is more specific than a directory) takes precedence. Although among the different conflict-resolution policies that can be thought of (see Samarati and De Capitani di Vimercati 2001 for a deeper treatment), some solutions may appear more natural than others, none of them represents “the perfect solution.” Whichever approach we take, we will always find one situation for which the approach does not fit. On the one side, support of negative authorizations does not come free; there is a price to pay in terms of authorization management and less clarity of the specifications. On the other side, the complications brought by negative authorizations are not due to negative authorizations themselves, but to the different semantics that the presence of permissions and denials can have—that is, to the complexity of the different real-world scenarios and requirements that may need to be captured. There is, therefore, a trade-off between expressiveness and simplicity. Consequently, current systems try to keep it simple by adopting negative authorizations for exception support, imposing specific conflict-resolution policies, or supporting a limited form of conflict resolution.
- *Administrative policies.* Because access control systems are based on access rules defining which accesses are (or are not) to be allowed, an administrative policy is needed to regulate the specification of such rules—that is, define who can add, delete, or modify them. Administrative policies are one of the most important, though less understood, aspects in access control. Indeed, they have usually received little consideration, and, while it is true that a simple administrative policy would suffice for many applications, it is also true that new applications (and organizational environments) would benefit from the enrichment of administrative policies. In theory, discretionary systems can support different kinds of administrative policies: centralized, in which a privileged user or group of users is reserved the privilege

of granting and revoking authorizations; hierarchical/cooperative, in which a set of authorized users is reserved the privilege of granting and revoking authorizations; ownership, in which each object is associated with an owner (generally the object’s creator), who can grant to and revoke from others the authorizations on its objects; and decentralized, in which, extending the previous approaches, the owner of an object (or its administrators) can delegate to other users the privilege of specifying authorizations, possibly with the ability of further delegating it. For its simplicity and large applicability the ownership policy is the most popular choice in today’s systems (see section on desiderata, above). Decentralized administration approaches can be instead found in the database management system contexts (see section on “Access Control in Database Management Systems”). Decentralized administration is convenient since it allows users to delegate administrative privileges to others. Delegation, however, complicates the authorization management. In particular, it becomes more difficult for users to keep track of who can access their objects. Furthermore, revocation of authorizations becomes more complex.

ACCESS CONTROL IN OPERATING SYSTEMS

We describe access control services in two of the most popular operating systems: Linux (e.g., www.redhat.com, www.suse.com) and Microsoft Windows 2000/XP (www.microsoft.com).

Access Control in Linux

We use Linux as a modern representative of the large family of operating systems deriving from UNIX. We signal the features of Linux that are absent in other operating systems of the same family.

Apart from specific privileges such as access to protected TCP ports, the most significant access control services in Linux are the ones offered by the file system. The file system has a central role in all the operating systems of the UNIX family, as files are used as an abstraction for most of the system resources.

User Identifiers and Group Identifiers

Access control is based on a user identifier (UID) and group identifier (GID) associated with each process. A UID is an integer value unique for each username (log-in name), the associations between usernames and UIDs is described in file `/etc/passwd`. A user connecting to a Linux system is typically authenticated by the log-in process, invoked by the program managing the communication line used to connect to the system (getty for serial lines, telnetd for remote telnet sessions). The log-in process asks the user for a username and a password and checks the password with its hash stored in read-protected file `/etc/shadow`; a less secure and older alternative stores hashed password in the readable-by-all file `/etc/passwd`. When authentication is successful, the login process sets the UID to that of the authenticated user, before starting an instance of the program listed in `/etc/passwd` and associated with the

specific user entry (typically the program is a shell, such as `/bin/bash`). Users in Linux are members of groups. Every time a user connects to the system, together with the UID, a primary GID is set. The value of the primary GID to use at log in is defined in file `/etc/passwd`. Group names and additional memberships in groups are instead defined in file `/etc/group`. Command `newgrp` allows users to switch to a new primary GID. If the user is listed in `/etc/group` as belonging to the group she chooses as the new primary GID, the request is immediately executed; otherwise, for groups having a hashed password stored in `/etc/group`, the primary GID can be changed after the password has been correctly returned. However, group passwords are deprecated, as they easily lead to lapses in password management.

Processes are usually assigned the UIDs and GIDs of their parent processes, which implies that each process acquires the UID and GID associated with the log-in name with which the session was started. The process UID is the central piece of information for the evaluation of the permitted actions. There are many operations in the system that are allowed only to the root user, whose value of UID is equal to zero. The *root* user represents the owner of the system who supervises all the activities. For instance, the TCP implementation allows user *root* only to open ports below 1024.

Files and Privileges

In the Linux file system, each file is associated with a UID and a GID, which typically represent the UID and the primary GID of the process that created the file. UID and GID associated with a file can be changed by commands *chown* and *chgrp*. The privileges associated with each file are nine: three groups of three privileges each, that is *read*, *write*, and *execute* privileges are defined at level of *user*, *group*, and *other*. The privileges defined at the level of *user* are the actions that will be permitted to processes having the same UID as the file; the privileges defined at the level of *group* are granted to processes having the same GID as the file; the privileges at the level of *other* are for processes that share neither the UID nor the GID with the file. The privileges are commonly represented, in the result of `ls -l` command, as a string of nine characters (preceded by a character representing the file type). The string presents first the three *user* privileges, then *group*, and finally *other*, in the order: *read*, *write*, and *execute*. Each privilege is represented by a single letter: *r* for *read*; *w* for *write*; and *x* for *execute*; the absence of the privilege is represented by character *-*. For instance, `rwxr-xr-` means that a process having as UID the same UID as the file has all the three privileges, a process with the same GID can read and execute (but not write) the file, and remaining processes can only read the file. When a user belongs to many groups, all the corresponding GIDs are stored in a list in the process descriptor of her processes beside the primary GID. When the policy needs to be evaluated, all the groups in the list are considered: if the GID of the file is the primary GID, or appears anywhere in the list, group access privileges apply. It is important to note that some operating systems of the UNIX family store only the primary GID within the process descriptor.

The semantics of privileges may be different depending on the type of the file on which they are specified. In particular, for directories, the *execute* privilege represents the privilege to access the directory; *read* and *write* privileges permit, respectively, to read the directory content and to modify it (adding, removing, and renaming files). Privileges associated with a file can be updated via the *chmod* command, which is usable by the file owner and by user *root*.

Additional Security Specifications

The file system offers three other privileges on files: *save text image (sticky bit)*, *set user ID (setuid)*, and *set group ID (setgid)*. The *sticky bit* privilege is useful only for directories, and it allows only the owner of the file, the owner of the directory, and the root to remove or rename the files contained in the directory, even if the directory is writable by all. The *setuid* and *setgid* privileges are particularly useful for executable files, in which they permit setting the UID and the GID, respectively, of the process that executes the file to that of the file itself. These privileges are often used for applications that require a higher level of privileges to accomplish their task (e.g., users change their passwords with the *passwd* program, which needs read and write access on file `/etc/shadow`). Without the use of these bits, enabling a process started by a normal user to change the user's password would require explicitly granting the user the write privilege on the file `/etc/shadow`. Such a privilege could, however, be misused by users who could access the file through different programs and tamper with it. The *setuid* and *setgid* bits, by allowing the *passwd* program to run with root privilege, avoid such a security exposure. It is worth noticing that, while providing a necessary security feature, the *setuid* and *setgid* solutions are themselves vulnerable, as the specified programs run with root privileges—in contrast to the least privilege principle, they are not confined to the accesses needed to execute their task—and it is therefore important that these programs are *trusted* (Samarati and De Capitani di Vimercati 2001).

The *ext2* and *ext3* file systems, the most common ones in Linux implementations, offer additional Boolean attributes on files. Among them, there are attributes focused on low-level optimizations (e.g., a bit requiring a compressed representation of the file on the disk) and two privileges that extend access control services: *immutable* and *append-only*. The *immutable* bit specifies that no change is allowed on the file; only the user *root* can set or clear this attribute. The *append-only* bit specifies that the file can be extended only by additions at the end; this attribute can also be set only by *root*. Attributes are listed by command *lsattr* and can be modified by command *chattr*.

IP-Based Security

Linux offers several utilities exploiting IP addresses for authentication purposes. All of these solutions should be used with care, as IP addresses can be easily spoofed in a local network (Fielding et al. 1999) and therefore fool the access control system. For this reason, they are not enabled by default. Among these utilities, *rsh* executes remote shells on behalf of users; *rcp* executes copies involving

the file systems of machines in a network; and *nfs* permits sharing of portions of the file system on the network. For these applications, access control typically is based on a few relatively simple text files, which describe the computers that can use the service and the scope of the service; patterns can be used to identify ranges of names or addresses, and groups may be defined, but overall the access control features are basic. Secure solutions of the above applications (like the *ssh* application and the *scp* program offered within the same package) offer a greater degree of security, at the expense of computational resources, configuration effort, and in general less availability.

Security-Enhanced Linux

An important initiative in the context of access control for Linux is the Security-Enhanced Linux (SELinux) kernel module (Loscocco and Smalley 2001). This component, originally developed within a project sponsored by the National Security Agency, aims at introducing the services of mandatory access control (MAC) within the Linux environment. Access control in SELinux is realized extending the services of the traditional (DAC) Linux model, which uses the pair $\langle \text{UID}, \text{GID} \rangle$ of the process to evaluate the ACL of the requested resource; in SELinux, each access request, coming by a process characterized by its “process label” and operating on a resource characterized by its “resource label,” is allowed if it also satisfies the centralized mandatory policy (see the section on “Access Control Policies” for a brief overview on mandatory access control policies).

The policy is composed of a set of rules, following a relatively rich syntax. Rules specify the set of labels and the initial assignment of labels to resources and processes; rules also specify how labels can be changed and which are the constraints that every operation has to satisfy. Using the rule syntax, SELinux permits the specification of a fine-grained access control policy; in this way, Linux can adequately support the principle of “least privilege,” giving each process access only to the set of resources that the process needs to execute its function. The policy usually classifies applications into many distinct domains, each characterized by a label, providing to each application access only to the resources that are needed to fulfill its task. This is particularly important for the configuration of processes realizing network services, which are exposed to the input of external users and have often been used to gain access to a system, exploiting errors in the input processing functions. When a process managing a server is constrained to access only the resources that are needed to realize the service, the risk deriving from an error in the code is considerably reduced, and its exploitation by a malicious user is considerably more difficult.

A few obstacles have slowed the adoption of SELinux. The most important current issue is the complexity of the policy-definition phase. Moreover, users are often surprised by the denial of requests that are legitimate in the DAC model, but that now violate MAC policy rules. In some cases the policy was too strict; in others, the user behavior did not take into account the features of the novel access control model. Fortunately, Linux distributions are providing continuously improved policies, which come

preconfigured with the system in order to protect traditional services, and users are acquiring familiarity with the system. In addition, SELinux is going to be enriched by tools that will allow relatively easy access and manipulation of policies, in order to facilitate the adaptation of a predefined policy to the specific needs of a given environment.

In conclusion, SELinux is an interesting solution, which promises to have a significant impact on the security of the Linux operating system, as is testified by its growing presence; several important Linux distributions already provide this kernel module, activated by default. Also, the SELinux model is flexible enough to permit the realization of sophisticated MAC solutions, such as multilevel security, which can be of interest in several environments, such as databases (Jajodia and Sandhu 1991).

Access Control in Windows

We now describe the characteristics of the access control model of the Microsoft Windows 2000/XP operating system (msdn.microsoft.com). Most of the features we present were already part of the design of Microsoft Windows NT; we will clarify the features that were not present in Windows NT and that were introduced in Windows 2000. We use the term *Windows* to refer to this family of operating systems. We do not consider the family of Windows 95/98/ME operating systems.

Security Descriptor

One of the most important characteristics of the Windows operating system is its object-oriented design. Every component of the system is represented as an object, with attributes and methods. Any subject that can operate on an object (user, group, log-on session, and so on) is represented in Windows by a security identifier (SID), with a rich structure that manages the variety of active entities. In this scheme, it is natural to base access control on the notion that objects can be securable—that is, they can be characterized by a security descriptor that specifies the security requirements for the object (this corresponds to implementing access control with an access control list approach [Samarati and De Capitani di Vimercati 2001]). The main components of the security descriptor are the SIDs of the owner and of the primary group of the object, a discretionary access control list (DACL), and a system access control list (SACL). Almost all of the system objects are securable: files, processes, threads, named pipes, shared memory areas, registry entries, and so on. The same access control mechanism applies to all of them.

Access Control Entry

Each access control list consists of a sequence of access control entries (ACEs). An ACE is an elementary authorization on the object, with which it is associated by way of the ACL; the ACE describes the subject, the action, the type (allow, deny, or audit), and several flags (to specify the propagation and other ACE properties). The subject, called “trustee” in Windows, is represented by a SID. The action is specified by an access mask, a 32-bit vector (only part of the bits are currently used; many bits are left

unspecified for future extensions). Half of the bits are associated with access rights that are the same for every object type; these access rights can be divided into three families:

- *generic*: *read*, *write*, *execute*, and the union of all of them;
- *standard*: *delete*, *read_control* (to read the security descriptor), *synchronize* (to wait on the object until a signal is generated on it), *write_dac* (to change the DACL), and *write_owner* (to change the object's owner);
- *SACL*: *access_system_security* (a single access right to modify the SACL; the right is not sufficient, as the subject must also have the `SE_SECURITY_NAME` privilege). It cannot appear in a DACL.

The remaining 16 bits are used to represent access rights specific for the object type (directory, file, process, thread, and so on). For instance, for directories, access rights *open*, *create_child*, *delete_child*, *list*, *read_prop*, and *write_prop* apply.

Access Token

Each process or thread executed in the system is associated with an access token—that is, an object describing the security context. An access token describing the user is created after the user has been authenticated and it is then associated with every process executed on behalf of the user. The access token contains: the SID of the user's account; SIDs of the groups that have the user as a member; a log-on SID identifying the current logon session; a list of the privileges held by the user or by the groups; an owner SID; the SID of the primary group; and the default DACL, used when a process creates a new object without specifying a security descriptor. In addition, there are other components that are used for changing the identifiers associated with a process (called “impersonation” in Windows), and to apply restrictions.

Evaluation of ACLs

When a thread makes a request to access an object, its access token is compared with the DACL in the security descriptor of the resource. If the DACL is not present in the security descriptor, the system assumes that the object is accessible without restrictions. Otherwise, the ACEs in the DACL are considered one after the other, and for each one the user and group SIDs in the access token are compared with the one in the ACE. If there is a match, the ACE is applied. The order of ACEs in the DACL is extremely important, in fact the first ACE that matches will allow or deny the access rights in it. The following matching ACEs will only be able to allow or deny the remaining access rights. If the analysis of the DACL terminates and no allow/deny result has been obtained for a given access right, the system assumes that the right is denied (closed policy). As an example, with reference to Figure 6, for user Bob the second ACE will apply (as it matches the group Nurse in the thread's access token) denying Bob the execute and write accesses on object 1. The approach of applying the first ACE encountered corresponds to the use of a “position-based” criterion for resolving possible conflicts

Figure 6: Access control in Windows

(Samarati and De Capitani di Vimercati 2001). Although simple, this solution is quite limiting. First, it gives the users specifying the policy the complete burden of solving each specific conflict that may arise (not allowing them to specify generic high-level rules for conflicts). Second, it is not suitable if a decentralized administration (where several users can specify authorizations) has to be accommodated. Also, users should have explicit direct write privilege on the DACL to properly order the ACEs. However, doing so it would be possible for them to abuse the privilege and set the ACL in an uncontrolled way.

It is worth noting that an empty DACL (which returns no permissions) will deny all users the access to the object, whereas a null DACL (which returns no restrictions) would grant them all. Therefore, attention must be paid to the difference between the two.

The DACL is set by the object creator. When no DACL is specified, the default DACL in the access token is used by the system. The SACL is a sequence of ACEs like the DACL, but it can be modified only by a user who has the administrative privilege `SE_SECURITY_NAME`, and describes the actions that have to be logged by the system (i.e., if the ACE for a given right and SID is positive, the action must be logged; if it is negative, no trace will be kept); the access control system records access requests that have been successful, rejected, or both, depending on the value of the flags in the ACE elements in the SACL. Each monitored access request produces a new entry in the security event log.

System Privileges

A system privilege in Windows is the right to execute privileged operations, such as making a backup, debugging a process, increasing the priority of a process, increasing the storage quota, and creating accounts. All these operations are not directly associated with a specific system object, and they cannot conveniently be represented by ACEs in an object security descriptor. System privileges can be considered as authorizations without an explicit object. System privileges can be associated with user and group accounts. When a user is authenticated by the system, the access token is created; the access token contains

the system privileges of the user and of the groups in which the user is a member. Every time a user tries to execute a system's privileged operation, the system checks whether the access token contains the adequate system privilege. System privileges are evaluated locally: a user can have different system privileges on different nodes of the network.

Impersonation and Restricted Tokens

Impersonation is a mechanism that permits threads to acquire the access rights of a different user. This feature is similar to the *setuid* and *setgid* services of Linux, in which the change in user and group identifiers permits programs invoked by a user to access protected resources. In Windows, impersonation is also an important tool for client/server architectures. The server uses impersonation to acquire the security context of the client when a request arrives. The advantage is that, in a network environment, a user will be able to consistently access the resources for which the user is authorized, and the system will be better protected from errors in the protocol used for service invocation or in the server application.

Each process has an access token (created at log on) built from the profile of the authenticated user. An impersonating thread has two access tokens, the primary access token that describes the access token of the parent process, and the impersonation access token that represents the security context of a different user. Impersonation requires an adequate system privilege and it can be a very useful tool; Windows Server 2003 has introduced the possibility for applications to set restrictions on delegation, to minimize the risk that a server receiving the impersonation access token accidentally forwards it to another untrusted party, giving access to resources that would otherwise be protected.

Windows 2000 introduced primitives for the creation of restricted tokens. A restricted token is an access token for which some privileges have been removed, or restricting SIDs have been added. A restricting SID is used to limit the capabilities of an access token. When an access request is made and the access token is compared with the ACEs in the ACL, each time there is a match between the restricting SID in the token and the SID in an ACE, the ACE is considered only if it denies access rights on the object.

Inheritance

Some important securable objects contain other securable objects. As an example, folders in the New Technology File System (NTFS) file system contain files and other folders; registry keys contain subkeys. This containment hierarchy puts in the same container objects that are often characterized by the same security requirements. The hierarchy results are then extremely convenient because they permit an automatic propagation of security descriptions from an object to all the objects contained within it (see the section on desiderata). This feature is realized in Windows by access control inheritance.

A difference exists between Windows NT and Windows 2000 (and later) with respect to inheritance. In Windows NT there is no distinction between direct and inherited ACEs: inherited ACEs are directly copied into the object's ACL when the object is created or when a new

ACL is applied to an object. The result is that a change in an object's ACL is not propagated down the hierarchy to the objects that inherit it. In Windows 2000 (and later), ACL inheritance is managed "by reference," obtaining an automatic propagation of ACL updates to the inheriting objects (as users would probably expect). Also, Windows 2000 gives higher priority to ACEs directly defined on specific objects, by putting the inherited ACEs at the end of the DACL.

In Windows 2000 (and later), every ACE is characterized by three flags. The first flag is active if the ACE has to be propagated to descendant objects. The second and third flags are active only if the first flag is active. The second flag is active when the ACE is propagated to children objects without activating the first flag, thus blocking propagation to the first level. The third flag is active when the ACE is not applied to the object itself. In addition, in the security descriptor of a securable object there is a flag that permits the disabling of the application of inherited ACEs to the object.

ACCESS CONTROL IN DATABASE MANAGEMENT SYSTEMS

DataBase Management Systems (DBMSs) usually provide access control services in addition to those provided by the underlying operating systems (Bellovin 1989). DBMS access control allows references to the data model concepts and the consequent specification of authorizations dependent on the data and on the applications. Most of the existing DBMSs (e.g., Oracle Server, IBM DB2, Microsoft SQL Server, and PostgreSQL) are based on the relational data model and on the use of SQL (Structured Query Language) as the data definition and manipulation language (Bellovin 1989). The SQL standard provides commands for the specification of access restrictions on the objects managed by the DBMS. Here we illustrate the main SQL facilities with reference to the current version of the language, namely SQL:2003 (Database Language SQL 2003).

Security Features of SQL

SQL access control is based on user and role identifiers (Atzeni et al. 1999). User identifiers correspond to log-in names with which users open the DBMS sessions. DBMS users are defined by the DBMS in an implementation-dependent way and are usually independent from the usernames managed by the operating system; SQL does not define how OS users are mapped to SQL users. Roles, introduced in the SQL standard with SQL:1999, are "named collections of privileges" (Sandhu, Ferraiolo, and Kuhn 2000)—that is, named virtual entities to which privileges are assigned. By activating a role, users are enabled to execute the privileges associated with the role.

Users and roles can be granted authorizations on any object managed by the DBMS, namely: tables, views, columns of tables and views, domains, assertions, and user-defined constructs such as user-defined types, triggers, and SQL-invoked routines. Authorizations can also be granted to the public, meaning that they apply to all the user and role identifiers in the SQL environment. Apart from the drop and alter statements—which permit deletion and

modification of the schema of an object and whose execution is reserved for the object's owner—authorizations can be specified for any of the commands supported by SQL, namely: *select*, *insert*, *update*, and *delete* for tables and views (where the first three can refer to specific columns), and *execute* for SQL-invoked routines. In addition, other actions allow controlling references to resources; they are: *reference*, *usage*, *under*, and *trigger*. The *reference* privilege, associated with tables or attributes within, allows referring to tables/attributes in an integrity constraint: a constraint cannot be checked unless the owner of the schema in which the constraint appears has the *reference* privilege for all the objects involved in the constraint. This is because constraints may affect the availability of the objects on which they are defined, and therefore their specification should be reserved for those explicitly authorized. The *usage* privilege, which can be applied to domains, user-defined types, character sets, collations, and translations, allows the use of the object in one's own declarations. The *under* privilege can be applied to a user-defined type and allows subjects to define a subtype of the specified type. The *trigger* privilege, referring to a table, allows the definition of a trigger on the table.

In addition to authorizations to execute privileges on the different objects of the database management system, SQL also supports authorizations for roles. In particular, roles can be granted to other users and roles. Granting a role to a user means allowing the user to activate the role. Granting a role r' to another role r means permitting r to enjoy the privileges granted to r' . Intuitively, authorizations on roles granted to roles introduce chains of roles through which privileges can flow. For instance, consider the case in Figure 7, in which the rightmost three nodes are users, the remaining three nodes are roles, and an arc corresponds to an authorization of the incident node on the role source of the arc (e.g., Ann has an authorization for the Admin_Supervisor role). Although each of the users will be allowed to activate the role for which Ann has the authorization (directly connected in our illustration) she will enjoy the principles of all the roles reachable through a chain. For instance, when activating role Admin_Supervisor, Ann will enjoy, in addition to the privileges granted to this role, also the privileges granted to roles Secretary and Accountant.

Access Control Enforcement

The subject making a request is always identified by a pair $\langle uid, rid \rangle$, where *uid* is the SQL-session user identifier (which can never be null) and *rid* is a role name, whose value is initially null. Both the user identifier and the role

Figure 7: An example of role chains in SQL

identifier can be changed via the commands *set session authorization* and *set role*, respectively, whose successful execution depends on the specified authorizations. In particular, enabling a role requires the current user to have the authorization for the role. The current pair $\langle uid, rid \rangle$ can also change on execution of a SQL-invoked routine, where it is set to the owner of the routine (see the section on “Views and Invoked Routines”). An *authorization stack* (maintained using a “last-in, first-out” strategy) keeps track of the sequence of pairs $\langle uid, rid \rangle$ for a session. Every request is controlled against the authorizations of the top element of the stack. Although the subject is a pair, like for authorizations and ownership, access control always refers to either a user or a role identifier in mutual exclusion: it is performed against the authorizations for *uid* if the *rid* is null; it is performed against the authorizations for *rid*, otherwise. In other words, by activating a role a user can enjoy the privileges of the role while disabling her own. Moreover, at most one role at a time can be active: the setting to a new role rewrites the *rid* element to be the new role specified.

Administration

Every object in SQL has an owner, typically its creator (which can be set to either the *current_user* or *current_role*). The owner of an object can execute all privileges on it, or a subset of them in case of views and SQL-invoked routines (see the section on “Views and Invoked Routines”). The owner is also reserved the privilege to drop the object and to alter (i.e., modify) it. Apart from the drop and alter privileges, the execution of which is reserved for the object's owner, the owner can grant authorizations for any privilege on its objects, together with the ability to pass such authorizations to others (grant option).

A *grant* command, whose syntax is illustrated in Figure 8, allows the granting of new authorizations for roles (enabling their activation) or for privileges on objects. Successful execution of the command requires the grantor to be the owner of the object on which the privilege is granted, or to hold the grant option for it. The specification of all privileges, instead of an explicit privilege list, is equivalent to the specification of all the privileges, on the object, for which the grantor has the grant option. The *with hierarchy* option (possible only for the *select* privilege on tables) automatically implies granting the grantee the *select* privilege on all the (either existing or future) subtables of the table on which the privilege is granted. The *with grant option* clause (called *with admin option* for roles) allows the grantee to grant others the received authorization (as well as the grant option on it). No cycles of role grants are allowed.

The *revoke* statement allows revocation of (administrative or access) privileges previously granted by the revoker (which can be set to the *current_user* or *current_role*). Because of the use of the grant option, and the existence of derived objects (see the section on “Views and Invoked Routines”), revocation of a privilege can possibly have side effects, since there may be other authorizations that depend on the one being revoked. The options *cascade* and *restrict* dictate how the revocation procedure should behave in such a case: *cascade* recursively revokes all the authorizations that should not exist anymore if the requested

```

grant all privileges | <action>
on [ table ] | domain | collation | character set | translation | type <object name>
to <grantee> [{<comma> <grantee>}...]
[ with hierarchy option ]
[ with grant option ]
[ granted by <grantor> ]

```

```

grant <role granted> [{<comma><role granted>}...]
to <grantee> [{<comma><grantee>}...]
[ with admin option ]
[ granted by <grantor>]

```

```

revoke [ grant option for | hierarchy option for ] <action>
on [ table ] | domain | collation | character set | translation | type <object name>
from <grantee> [{<comma><grantee>}...]
[ granted by <grantor> ]
cascade | restrict

```

```

revoke [ admin option for ]
<role revoked> [{<comma><role revoked>}...]
from <grantee> [{<comma><grantee>}...]
[ granted by <grantor> ]
cascade | restrict

```

Figure 8: Syntax of the grant and revoke SQL statements

Figure 9: Authorizations before (a) and after (b) the cascade revocation of Bob's privilege

privilege is revoked; *restrict* rejects the execution of the revoke operation if other authorizations depend on it. To illustrate, consider the case in which user Ann creates a table and grants the select privilege, and the grant option on it, to Bob and Carol. Bob grants it to David, who grants it to Ellen, who grants it to Gary. Carol also grants the authorization to Frank. Assume for simplicity that all these grant statements include the grant option. Figure 9a illustrates the resulting authorizations and their dependencies, with a node for every user and an arc from the grantor to the grantee for every authorization. Consider now a request by Ann to revoke the privilege from Bob. If the revoke is requested with the option *cascade*, also the authorizations granted by Bob (who would no longer hold the grant option for the privilege) will be revoked, causing the revocation of David's authorization, which will recursively cause the revocation of the authorization David granted to Ellen. The resulting authorizations (and their dependencies) are illustrated in Figure 9b. Note that no recursive revocation is activated for Frank, because even if the authorization he received from Bob is deleted, Frank still holds the privilege with the grant option (received from Carol). By contrast,

if Ann were to request the revoke operation with the *restrict* option, the operation would be refused because of the authorizations dependent on it (those which would be revoked with the *cascade* option).

Views and Invoked Routines

Special consideration must be taken for authorizations for derived objects (views) and SQL-invoked routines, for which the owner creating them does not own the underlying objects used in their definition.

A view is a *virtual* table derived from base tables and/or other views. A view definition is an SQL statement whose result defines the content of the view. The view is virtual since its content is not explicitly stored, but it is derived, at the time the view is accessed, by executing the corresponding SQL statement on the underlying tables. A user/role can create a view only if it has the necessary privilege on all the views, or base tables, directly referenced by the view. The creator receives on the view the privileges that it holds on all the tables directly referenced by the view. Also, it receives the grant option for a privilege only if it has the grant option for the privilege on all the tables directly referenced by the view. If it holds a privilege on the view with the grant option, the creator can grant the privilege (and the grant option) to others. The grantees of such privileges need not hold the privileges on the underlying tables to access the view; access to the view requires only the existence of privileges on the view. Intuitively, the execution of the query computing the view is controlled against the authorizations of the view's owner (similarly to what the *suid* bit does in UNIX). Also, views provide a way to enforce finer-grained access (on specific tuples). For instance, a user can define a view `EU_Employees` on table `Employees` containing only those rows for which the

value of attribute nationality is equal to EU. She can then grant other users the *select* privilege on the view, thus allowing (and restricting) them access to information on employees within the European Union. Views are the only means to bypass an *all tuples* or *no tuple* access on tables. Although convenient, views are simply a trick for enforcing content-dependent fine-grained access control (which is not the main reason why they were developed), and as such limit results for this purpose: a different view should be defined for any possible content-dependent access restriction that should be enforced.

An SQL-invoked routine is an SQL-invoked procedure, or an SQL-invoked function, characterized by a header and a body. The header consists of a name and a, possibly empty, list of parameters. The body may be specified in SQL or, in the case of external routines, written in a host programming language. At object creation time, a user is designated as the *owner* of the routine. Analogously to what is required for views, to create an SQL-invoked routine, the owner needs to have the necessary privileges for the successful execution of the routine. The routine is dropped if at any time the owner loses any of the privileges necessary to execute the body of the routine. When a routine is created, the creator receives the *execute* privilege on it, with the grant option if it has the grant option for all the privileges necessary for the routine to run. If the creator of a routine has the *execute* privilege with the grant option, she can grant such a privilege, and the grant option on it, to other users/roles. The *execute* privilege on an SQL routine is sufficient for the users/roles gaining the privilege to run the routine (they need not have the privileges necessary for the routine to run; only the creator does). Intuitively, SQL routines provide a service similar to the *setuid/setgid* privileges in Linux and impersonation in Windows (controlling privileges with respect to the owner instead of the caller of a procedure).

ACCESS CONTROL FOR INTERNET-BASED SOLUTIONS

We here survey the most common security features for Internet-based solutions. Again, we illustrate the most popular representative of the different families. We will therefore look at the XACML access control language for regulating information and e-service accesses; Apache for Web-based solutions; and the Java 2 security model.

XML-Based Access Control Languages

An essential requirement of new Internet-wide security standards is that they should be able to apply to content created using also eXtensible Markup Language (XML) (Bradley 2002). XML has been adopted widely for a great variety of applications and types of content. Examples of XML-based markup languages are Security Assertion Markup Language (SAML) used to exchange security credentials among different parties, Geography Markup Language (GML), Wireless Markup Language (WML), Physical Markup Language (PML),

and Mathematical Markup Language (MathML), just to name a few. XML is also at the basis of interoperability protocols used to integrate applications across the Internet, such as Web Services protocols (e.g., SOAP [Simple Object Access Protocol], WSDL [Web Services Description Language], and UDDI [Universal Description, Discovery, and Integration] [Newcomer 2002]). It is therefore of paramount importance to provide integrity, confidentiality and other security benefits to entire XML documents or portions of these documents in a way that does not prevent further processing by standard XML tools.

Traditionally, XML security has developed along two distinct though related lines of research, corresponding to two facets of the XML security notion. The first facet defines XML security as a set of security techniques (access control [Samarati and De Capitani di Vimercati 2001], differential encryption [XML Encryption Syntax and Processing, W3C Recommendation 2002], digital signature [XML-Signature Syntax and Processing, W3C Recommendation 2002]) tightly coupled with XML to maintain the main features of the XML semistructured data model while adding to it all the necessary security capabilities. A second important facet of XML security deals with models and languages specifying and exchanging access control policies to generic resources, which may or may not comply with the XML data model. Initially, XML-based access control languages were introduced only for the protection of resources that were themselves XML files (Damiani et al. 2002; Gabillon 2004). Some proposals instead use XML to define languages for expressing protection requirements on any kind of data/resources (Ardagna et al. 2004; Godik and Moses 2004). One of the most relevant XML-based access control languages is the eXtensible Access Control Markup Language (XACML) (Godik and Moses 2004; Moses 2005). XACML is the result of an OASIS standardization effort proposing an XML-based language to express and interchange access control policies. XACML is designed to express authorization policies in XML against objects that can themselves be identified in XML.

XACML

The main concepts of interest in the XACML policy language are: policy, policy set, and rule.

Policy Syntax and Semantics. An XACML policy has, as the root element, either Policy or PolicySet. A PolicySet is a collection of Policy or PolicySet. An XACML policy consists of a target, a set of rules, a rule combining algorithm, and an optional set of obligations. A target consists of a simplified set of conditions for the subject, resource, and action that must be satisfied for a policy to be applicable to a given request. If a policy applies to all entities of a given type, that is, all subjects, actions, or resources, an empty element, named AnySubject, AnyAction, or AnyResource, respectively, is used. The components of a rule are target, effect, and condition. The optional target element defines the set of resources, subjects, and actions to which the rule is intended to apply. The effect of the rule can be permit or deny. The condition

represents a Boolean expression that may further refine the applicability of the rule. A rule-combining algorithm is used for reconciling the decisions each rule makes. The final decision value, called “authorization decision,” is the value of the policy as defined by the rule-combining algorithm. XACML defines the following different combining algorithms.

- *Deny overrides*. It states that if there exists a rule that evaluates to deny or if all rules evaluate to not applicable, the result is deny. If all rules evaluate to permit, the result is permit. If some rules evaluate to permit and some evaluate to not applicable, the result is permit.
- *Permit overrides*. It states that if there exists a rule that evaluates to permit, the result is permit. If all rules evaluate to not applicable, the result is deny. If some rules evaluate to deny and some evaluate to not applicable, the result is deny.
- *First applicable*. It states that each rule has to be evaluated in the order in which it appears in the policy. For each rule, if the target matches and the conditions evaluate to true, the result is the effect (permit or deny) of such a rule.
- *Only-one-applicable*. It states that if more than one rule applies, the result is indeterminate. If no rule applies, the result is not applicable. If only one policy applies, the result coincides with the result of evaluating that rule.

According to the selected combining algorithm, the authorization decision can be permit, deny, not applicable (when no applicable policies or rules could be found), or indeterminate (when some errors occurred during the access control process). An obligation is an action that has to be performed in conjunction with the enforcement of an authorization decision. For instance, an obligation can state that all accesses on medical data have to be logged. Note that only policies that are evaluated and have returned a response of permit or deny can return obligations. In other words, obligations associated with a policy that evaluates indeterminate or not applicable are ignored.

An important feature of XACML is that a rule is based on the definition of attributes corresponding to specific characteristics of a subject, resource, action, or environment. Attributes are identified by the Subject Attribute Designator, ResourceAttributeDesignator, Action Attribute Designator, and EnvironmentAttributeDesignator elements. These elements use the AttributeValue element to define the requested value of a particular attribute. Alternatively, the AttributeSelector element can be used to specify where to retrieve a particular attribute. Note that both the attribute designator and AttributeSelector elements can return multiple values. For this reason, XACML provides an attribute type, called “bag,” corresponding to an unordered collection of values that can contain duplicated values for a particular attribute. In addition, XACML defines other standard value types such as string, Boolean, integer, time, and so on. Together with these attribute types, XACML also defines operations to be performed on the

different types such as equality operation, comparison operation, string manipulation, and so on.

Policy example. As an example of an XACML policy, suppose that an e-commerce site defines a high-level policy stating that “any user playing the role Subscribers can read the discount_products if the Acme fidelity card is attached to the request.” Figure 10 illustrates the XACML policy corresponding to this high-level policy. The policy applies to requests on the `www.example.com/products/discount.html` resource. The policy has one rule with a target that requires a read action, a subject with role Subscribers, and a condition that applies only if the subject has the Acme fidelity card.

Apache Access Control

The Apache HTTP server (www.apache.org) allows the specification of access control rules via a per-directory configuration file usually called `.htaccess` (Apache HTTP server version 1.3). The `.htaccess` file is a text file including access control rules (called “directives” in Apache) that affect the directory in which the `.htaccess` file is placed and, recursively, directories below it (see the section on “Evaluation of `.htaccess` Files” for more details). Figure 11 illustrates a simple example of an `.htaccess` file.

Access control directives, whose specification is enabled via module `mod_access`, can be either host-based (they can refer to the client’s host name and IP address, or other characteristics of the request) or user-based (they can refer to usernames and groups thereof). We start by describing such directives and then we illustrate how the `.htaccess` files including them are evaluated.

Host-Based Access Control

Both permissions and denials can be specified, by using the Allow (for permissions) and Deny (for denials) directives, which can refer to location properties or environment variables of the request. *Location-based* specifications have the form:

```
Allow from host-or-network/all
Deny from host-or-network/all
```

where *host-or-network* can be: a domain name (e.g., `acme.com`); an IP address or IP pattern (e.g., `155.50.`); a network/netmask pair (e.g., `10.0.0.0/255.0.0.0`); or a network/*n* CIDR mask size, where *n* is a number between 1 and 32 specifying the number of high-order 1 bits in the netmask. For instance, `10.0.0.0/8` is the same as `10.0.0.0/255.0.0.0`. Alternatively, value `all` denotes all hosts on the network.

Variable-based specifications have the form:

```
Allow from env = env-variable
Deny from env = env-variable
```

where *env-variable* denotes an environment variable. The semantics is that the directive (allow or deny) applies if *env-variable* exists. Apache permits the setting of environment variables based on different attributes of the HTTP client request using the directives provided by module

```

```

Figure 10: A simple example of an XACML policy

mod_setenvif. The attributes may correspond to various HTTP request header fields (see RFC 2616 [Fielding et al. 1999]) or to other aspects of the request. The most commonly used request header field names include: User-Agent

(the user agent originating the request) and Referer (the Uniform Resource Identifier [URI] of the document from which the URI in the request was obtained). For instance, in Figure 11, directive SetEnvIf sets "internal_site" if the

```

SetEnvIf Referer www.mydomain.org internal_site
AuthName "user-based restriction"
AuthType Basic
AuthUserFile /home/mylogin/.htpasswd
AuthGroupFile /home/mylogin/.htgroup
Order Deny,Allow
Deny from all
Allow from acme.com
Allow from env= internal_site
Require valid-user
Satisfy any
<FilesMatch public_access.html>
Allow from all
</FilesMatch>

```

Figure 11: A simple example of an .htaccess file

referring page was in the www.mydomain.org Web site. The “Allow from env = internal_site” directive, then, permits access if the referring page matches the given URI.

Access control evaluates the content of file .htaccess to determine whether a request should be granted or denied. The Order directive controls the order in which the Deny and Allow directives must be evaluated (thus allowing users to dictate the conflict resolution policy to be applied) and defines the default access state. There are three possible orderings:

- Deny,Allow. The deny directives are evaluated first, and access is allowed by default (open policy). Any client that does not match a deny directive *or* matches an allow directive is granted access.
- Allow,Deny. The allow directives are evaluated first and access is denied by default (closed policy). Any client that does not match an allow directive *or* matches a deny directive is denied access.
- Mutual-failure. Only clients that do not match any Deny directive *and* match an Allow directive are allowed access.

For instance, the .htaccess file in Figure 11 states that all hosts in the acme.com domain and requests with a referring page in the www.mydomain.org Web site are allowed access; all other hosts are denied access.

User-Based Access Control

Besides host-based access control rules, Apache includes a module, called mod_auth, that enables user authentication (based on usernames and passwords) and enforcement of user-based access control rules. Usernames and associated passwords are stored in a text *user file*, reporting pairs of the form “username:MD5-encrypted password.” Command htpasswd is used to modify the file (i.e., add new users or change passwords) as well as to create/rewrite it (a -c flag rewrites the file as new). The command has the form:

```
htpasswd [-c] filename username
```

where *filename* is the full path name of the user file and *username* is the name of the user we are creating. Upon entering the command, the system will ask to specify the password (as usual asking its input twice to avoid insertion errors). An alternative to the text user file provided by module mod_auth, is given by modules mod_auth_db and mod_auth_dbm. With these modules, the usernames and passwords are stored in Berkeley DB files and DBM type database files, respectively.

To define user-based restrictions, a name can be given to the portion of the file system access that requires authentication. This portion, called “realm,” corresponds to the subtree rooted at the directory containing the .htaccess file.

The main directives to create realms are:

- AuthName, to give a name to the realm. The realm name will be communicated to users when prompted for the log-in dialog.
- AuthType, to specify the type of authentication to be used. The most common method, implemented by mod_auth is Basic, which sends the password from the client to the server unencrypted (with a base64-encoding). A more secure, but less common alternative is the Digest authentication method, implemented by module mod_auth_digest, which sends the server a one-way hash (MD5 digest) of the username:password pair, combined with a nonce provided by the server. This Digest authentication method is supported by all recent versions of common browsers (e.g., MS Internet Explorer, Mozilla Firefox, and Opera).
- AuthUserFile, to specify the absolute path of the file that contains usernames and passwords. Note that the user file containing names and passwords does not need to be in the same directory as the .htaccess file.
- AuthGroupFile, to specify the location of a *group file*, and therefore provide support for access rules specified for groups. The group file is a list of entries of the form

```
group-name: username1 username2 username3.....
```

where *group-name* is the name associated with the group to which the specified usernames are declared to belong, and each of the usernames appearing in the list must be in the user file (i.e., be an existing username).

The four directives above allow the server to know where to find the usernames and passwords and which authentication protocol has to be used. User-based access rules are specified with a directive “require” that can take three forms:

- require user *username1 username2 ...usernameN*—only usernames “username1 username2...usernameN” are allowed access;
- require group *group1 group2...groupM*—only usernames in groups “group1 group2...groupM” are allowed access;
- require valid-user—any username in the user file is allowed access.

Host-Based and User-Based Interactions and Finer-Grained Specifications

Host- and user-based access directives are not mutually exclusive, and they can both be used to control access to the same resource. The directive *satisfy* allows the specification of how the two sets of directives should interact. Satisfy takes one argument whose value can be either all or any. Value *all* requires both user-based and host-based directives to be satisfied for access to be granted, whereas for value *any*, it is sufficient that either one is satisfied for access to be granted.

As already stated, all the directives specified in *.htaccess* apply to the file system subtree rooted at the directory that contains the specific *.htaccess* file unless overridden. In other words, an *.htaccess* file in a directory applies to all the files directly contained in the directory and recursively propagates to all its subdirectories unless an *.htaccess* has been specified for them (most specific takes precedence). Apache 1.2 (and later) supports finer-grained rules allowing the specification of access directives on a per-file basis by including FilesMatch section of the form "`<FilesMatch reg-exp>directives</FilesMatch>`," with the semantics that the directives included in the FilesMatch section apply only to the files with a name matching the regular expression specified. Also, directives can be specified on a per-method basis, by using a Limit section of the form "`<Limit list of access methods>directives</Limit>`," with the semantics that the directives included in the Limit section apply only to the accesses listed (again overriding the directives specified in the *.htaccess* file). As an example, directive

```
<Limit get post put>
    require valid-user
</Limit>
```

would allow any authenticated user to execute methods get, post, and put. The directive does not apply to other operations.

Evaluation of .htaccess Files

As mentioned previously, the file *.htaccess* is used to control accesses to the files in a directory. Therefore, whenever an access request to a file is submitted, the Apache HTTP server starts checking in the top directory for an *.htaccess* file, and then checks each subdirectory until it reaches the directory that contains the requested file appears (Coar 2001). All *.htaccess* files found during this process (called "directory walk") are processed and merged, thus resulting in a set of directives that apply to the requested file. More precisely, the directives specified in the *.htaccess* files have to be processed if they belong to the categories (AuthConfig, FileInfo, Indexes, Limit, and Options) listed in the AllowOverride list specified in a server configuration file. These directives are then merged according to the most specific principle—that is, directives within *.htaccess* files in subdirectories may change or nullify the effects of the directives within *.htaccess* files of parent directories. As an example, suppose that the access request for `http://acme.com/Department1/welcome.html` resolves to the file `/home/myaccount/www/Department1/welcome` and that statement AllowOverride All has been

specified. In this case, the Apache HTTP server merges *all* directives included in the *.htaccess* files of directories: `/`; `/home`; `/home/myaccount`; `/home/myaccount/www`; and `/home/myaccount/www/Department1`.

Java 2 Security Model

Java is both a modern object-oriented programming language and a complex software architecture. Java has been developed by Sun Microsystems and is currently one of the most important solutions for the construction of applications in a network environment. Java offers sophisticated solutions for the design of distributed and mobile applications, in which the software can be partitioned on distinct nodes and downloaded from one node to be executed on another.

Since its introduction, Java designers have carefully considered the security implications of an architecture for which executable code could be downloaded from the network, possibly from untrusted hosts. The first security model of Java, the one associated with Java Development Kit version 1.0 (JDK 1.0), was based on the construction of a *sandbox*, a restricted environment for the execution of downloaded code, with rigid restrictions on the set of local resources that could be used (e.g., with no access to the file system and with limits on network access).

The main problem of the JDK 1.0 security model was the limited granularity and the availability of a single policy for all downloaded code. JDK 1.0 would let programmers revise the access control services and implement their own version; but the implementation of access control services is complex, expensive, and delicate, making it unfeasible for most applications.

The evolution of Java to version 2 gave the opportunity to revise the security model and significantly improve it. We describe the Java 2 Security Architecture. A full and authoritative description of the architecture appears in (Gong 1999).

We observe that the security services of Java are not related to the access control system of the host operating system. This design choice derives from the requirement to make Java a fully portable execution environment, which does not depend on the services of the underlying system. The Java environment will have to be properly protected on the host system, as write access to the implementation of the Java Virtual Machine, or to its configuration, would permit the bypassing of any security mechanism within the Java environment.

We focus our presentation on the security model that associates permissions with pieces of Java code. This code-centric model adequately supports the security of mobile code. We do not describe the Java Authentication and Authorization Service (JAAS, since Java 2 v. 1.4 integrated with the JDK), a set of Java packages that offer services for user authentication and management of access control rights. JAAS extends the native Java 2 security model, using all the mechanisms presented here.

It is important to observe that the Microsoft .NET architecture presents many features that are similar to those offered by Java, with a standard virtual machine environment (the common language runtime, CLR) responsible

for the execution of portable code in a network-centered environment. In terms of security, the design of the .NET architecture has taken advantage of the experience in the design of Java and offers a security model that presents most of the functions appearing in the Java 2 model; a distinctive feature is the strong integration of the .NET security services with all the features of the Windows access control model. We refer the reader to the description available on the Microsoft Web site; the understanding of the services of the Java 2 model should greatly facilitate the comprehension of the design of the .NET security model.

Security Policy

The security policy describes the behavior that a Java program should exhibit. Each security policy is composed of a list of entries (an access control list) that defines the permissions associated with Java classes and applications. There is a standard security policy defined for the whole Java installation, and each user can personalize it extending the ACL in several ways—for example, writing a specific file in the personal home directory. The security policy is represented by a Policy object.

Each entry in the security policy describes a piece of Java code and the permissions that are granted to it. Each piece of Java code is described by a URL and a list of signatures (represented in Java by a CodeSource object). The URL can be used to identify both local and remote code; with a single URL it is also possible to characterize single classes or complete collections (packages, Java Archive [JAR] files, directory trees). The signatures may be applied on the complete URL or on a single class within a collection. Because URLs may identify collections, it is important to support implication among CodeSource objects (e.g., `www.xmlsec.org/classes/` implies `www.xmlsec.org/classes/xml.jar`).

Permissions

Permissions describe the access rights that are granted to pieces of Java code. Each permission is represented by an instance of the abstract class `Permission`. Permissions are typically represented by a target and an action (e.g., file target `/tmp/javaApp1/buffer` and action `write`). There are permissions that are characterized only by the target, with no action (e.g., target `exitVM` for the execution of `System.exit`). The `Permission` class is specialized by many concrete classes, which define a hierarchy. Direct descendants of `Permission` are `FilePermission` (used to represent access rights on files), `SocketPermission` (used to control access to network ports), `AllPermission` (used to represent with a single permission the collection of all permissions), and `BasicPermission` (typically used as the base class for permissions with no action).

The current security model considers only positive authorizations. The rationale is that the evaluation is more efficient and the model is clearer for the programmer. However, no fundamental restriction has been introduced, and the model could evolve to support negative authorizations (in a future version of Java, or in an ad hoc security mechanism built for a specific application).

It is also interesting to note that permissions refer to classes and not to instance objects. A model granting

permissions to objects would have offered finer granularity, but it would have also been more difficult to manage. Specifically, objects exist only at run-time, whereas the security policy is static, and it is not convenient to specify in it permissions at the level of objects.

To manage sets of permission, the Java model offers class `PermissionCollection`, which groups permissions of the same category (e.g., file permissions). Class `Permissions` represents collections of `PermissionCollection` objects, that is, collections of `Permission` objects.

Access Control

In the Java 2 architecture, permissions, which are represented by various `Permission` objects, are not directly associated with classes. Class `ProtectionDomain` realizes the link between classes and permissions. A protection domain contains classes and objects that inherit the permissions granted to the domain itself. For instance, a protection domain can be defined as follows:

```
ProtectionDomain domain =
    new ProtectionDomain(codesource,permissions);
```

This piece of code creates a new `ProtectionDomain` with the given `codesource` and permissions.

The security policy specifies permissions for a URL that may correspond to many classes; all the classes refer to the same protection domain. There is a predefined *system* domain that associates permission `AllPermissions` to all the classes in the core of the Java architecture.

In Java 2, access control is realized at two levels: `SecurityManager` and `AccessController`. At the higher level, class `SecurityManager` is responsible for evaluating access restrictions and is invoked whenever permissions have to be verified. In JDK 1.0 the class was abstract, forcing each Java implementation to provide its own realization. In Java 2 the class is concrete, and a standard implementation is part of the run-time environment. The main method of class `SecurityManager` is `checkPermission`. In JDK 1.0 the check on permissions was realized by ad hoc methods (e.g., to check for read permission on a file, method `checkRead` was used). Java 2 maintains all the previous methods for backward compatibility, but it uses a single method, `checkPermission`, for every permission type. This increases the flexibility of the security model, as the introduction of novel permissions can be managed with relative ease, without the need to modify the implementation of the `SecurityManager`.

The method `checkPermission` determines whether the permission that appears as the first parameter of the method is granted. If the check is successful, the method returns the control to the caller; otherwise it generates a security exception.

The method `checkPermission` in the standard `SecurityManager` immediately calls the method `checkPermission` of the class `AccessController`. The class `AccessController` is a final (i.e., unmodifiable) class that represents the security policy that Java 2 supports by default. This distinction into two levels is motivated by two conflicting requirements, each managed at a separate level. On the one hand, there is the need for flexibility, for applications that may need a different security policy; for these

applications it would be possible to realize a specialized implementation of the Security Manager class, which would then be automatically invoked for security checks by Java classes, that call the services of the SecurityManager. On the other hand, applications may prefer to have a guarantee that the security model used is the default one for Java 2; in this case, applications may opt to refer directly to the services of the AccessController class.

Access control is evaluated in the execution environment, which is characterized by an array of ProtectionDomain objects. There may be more than one ProtectionDomain object, as Java classes may invoke the services of classes that belong to different domains. The problem is then to decide how to consider the permissions of different domains in the execution environment. The solution used in Java 2 is to consider as applicable permissions only those that belong to the intersection of all the domains. Consequently, when checkPermission runs, it considers all the ProtectionDomain objects, and if there is at least one domain that has not been granted the permission being checked, a security exception is generated. The rationale for this policy is that this is the safest approach, realizing the minimum privilege principle.

There is an exception to the above behavior, which requires the use of the method doPrivileged of the class AccessController. The method doPrivileged creates a separate execution environment, which considers only the permissions of the ProtectionDomain associated with the code itself. The goal of this method is analogous to that of the *setuid* mechanism in Linux, in which the privileges of the owner of the code are granted to the user executing it. For instance, a changePassword method that requires write permission on a password file can be realized within a doPrivileged method. The advantage of this mechanism with respect to the *setuid* mechanism is that in Java it is possible to restrict with a very fine granularity the Java statements that have to be executed in a privileged mode, whereas in Linux the privileges of the owner are available to the executor for the complete run of the program (in contrast to the least privilege). Finally, we consider how the security model integrates with the inheritance mechanism that characterized the Java object model. Two classes, one of which is a specialization of the other may belong to distinct domains. When a method of a subclass is invoked, the effective ProtectionDomain is the one for which the method is implemented; if the method is simply inherited from the superclass, with no redefinition, the domain of the superclass is considered; if the method is redefined in the subclass, the domain of the subclass is instead used by the checkPermission method.

DISCUSSION AND CONCLUSION

In this chapter, we discussed the basic concepts of access control and illustrated the main features of the access control services provided by some of the most popular operating systems, database management systems, and network-based solutions. Recent proposals addressing access control in open and dynamic environments take into consideration the fact that a server may receive requests not just from the local community of users, but also from remote, previously unknown users. The

traditional separation between authentication and access control cannot be therefore applied in this context, and alternative access control solutions should be devised.

To this purpose, trust management has received considerable attention in the research community. In this case, access control is no longer based on users' identities, but on their attributes/properties (Bonatti and Samarati 2002). These properties are typically represented through digital certificates (credentials). A digital certificate is basically a statement certified by a given entity that can be used to establish properties of the certificate holder. Trust between two interacting parties is then established on the basis of parties' properties, which are proven through the disclosure of digital certificates.

To adopt digital certificates for access control, it is necessary to develop authorization languages and systems, for which parties must be able to state and enforce access rules based on credentials and communicate these rules to their counterpart to correctly establish a negotiation. The negotiation consists of a series of requests for credentials and counter-requests on the basis of the parties' policies. Different trust negotiation strategies have been proposed in the past few years, which try to balance two different needs (Seamons, Winslett, and Yu 2001). On the one hand, the user is willing not to release credentials to the remote and unknown server if it is not necessary for accessing the requested resource, as credentials may contain sensitive information. On the other hand, the server does not want to communicate to the unknown user the policies it is enforcing for granting access to the resources. It is therefore necessary to introduce the definition of policies, both client and server side, to control the release of credentials, and to establish a negotiation process between the parties to gain an agreement.

Although current solutions supporting credential-based policies are technically mature enough to be used in practical scenarios, there are still issues that need to be investigated to enable more complex applications such as (De Capitani di Vimercati and Samarati 2005): the definition of common languages, dictionaries, and ontologies to provide parties with a means to understand each other with respect to the properties they enjoy (or request the counterpart to enjoy); the development of a mechanism that explains why access requests are eventually denied, or—better—how to obtain the desired permissions; and the development of a mechanism that returns the information about which conditions need to be satisfied for the access to be granted, without disclosing “too much” of the underlying security policy, which might also be regarded as sensitive information.

GLOSSARY

Authentication: Means of establishing the validity of a claimed identity.

Authorization: The right granted to a user to exercise an action (e.g., read, write, create, delete, and execute) on certain objects.

Availability: A requirement intended to guarantee that information and system resources are accessible to authorized users when needed.

Confidentiality: The assurance that private or confidential information not be disclosed to unauthorized users.

Credential: Certified property of the holder, issued by an authorized party.

DAC: Discretionary Access Control.

Data Integrity: A requirement that information is not modified improperly.

Group: A set of users.

Integrity: Information has integrity when it is accurate, complete, and consistent. (See *Data Integrity* and *System Integrity*).

MAC: Mandatory Access Control.

RBAC: Role-Based Access Control.

Role: A job function within an organization that describes the authority and responsibility related to the execution of an activity.

Secrecy: A requirement that released information be protected from improper or unauthorized release.

Security: The combination of integrity, availability, and secrecy.

Security Mechanism: Low-level software and/or hardware functions that implement security policies.

Security Policy: High-level guidelines establishing rules that regulate access to resources.

SELinux: Security-Enhanced Linux.

Subject: An active entity that can exercise access to the resources of the system.

User: A person who interacts directly with a system.

XACML: eXtensible Access Control Markup Language.

XML: eXtensible Markup Language.

INTRODUCTION

The importance of data security in networked computer environments has been emphasized since the beginning of such networks (IBM 1970; National Bureau of Standards 1977; Wasserman 1969). One long-recognized key to maintaining data security is the “consistent verification of both the identification and authorization of the individual subject and terminal, depending upon the degree of security required, *each time* an attempt is made to access restricted data” (IBM 1970). IBM listed “three basic ways to identify a terminal subject: 1) By something he knows or memorizes, ... 2) By something he carries, ... 3) By a personal physical characteristic.” The process of recognizing subjects by personal physical characteristics is now referred to as “biometric authentication,” or more simply “biometrics.” These technologies have become far more available and practical since first being introduced in the 1960s and are now important alternatives to “something he knows or memorizes” (personal identification numbers [PINs] and passwords) or “something he carries” (fob, key, or badge) for recognizing individual network subjects and connecting them with their authorizations. In this chapter, we will look at these technologies in general, and give case studies of some specific applications of biometrics to computer network security.

FUNDAMENTAL CONCEPTS

“Biometric authentication” can be defined as the automated recognition of individual persons based on distinguishing biological (usually anatomical) and behavioral traits. The field is a subset of the broader field of human identification science. At the current level of technology, DNA analysis is a laboratory technique not fully automated and requiring human processing, so it is not considered “biometric authentication” under this definition. Examples of technologies currently in use to control access to computer networks or physical spaces containing computer network hardware include: fingerprint, speaker,

face, hand geometry, hand vein, and iris recognition. Some techniques (such as iris recognition) are more biologically based, some (such as speaker recognition) are more behaviorally based, but all techniques are influenced by both behavioral and biological elements.

“Biometric authentication” is frequently referred to simply as “biometrics,” although this word has historically been associated with the statistical analysis of general biological data. *Biometrics*, like *genetics*, is usually treated as singular. It first appeared in the vocabulary of physical and information security around 1980 (Pollack 1981) as a substitute for the earlier descriptor, “automatic personal identification,” in use in the 1970s. Biometric systems recognize “individual persons” by recognizing “bodies.” The distinction between person and body is subtle (Baker 2000; Martin and Barresi 2003), but it is of key importance in understanding the inherent capabilities and limitations of these technologies. In this chapter, we will adopt the conventional terms *individual*, *person*, and *subject*, although we really mean “body.” In our context, biometrics deals with computer recognition of signal patterns created by body behaviors and biological structures and is usually associated more with the field of computer engineering and statistical pattern analysis than with the behavioral or biological sciences.

The perfect biometric measure for all applications would possess the following five properties:

- Distinctive: Different from individual to individual
- Repeatable: Similar across time for each individual
- Accessible: Easily displayed to a sensor
- Acceptable: Not objectionable to persons
- Universal: Possessed by and observable on all people

Unfortunately, no biometric measure has all of the above properties: there are great similarities among the sensor patterns generated by different individuals; measures associated with each individual change over time; some physical limitations prevent display; “acceptability” is in

the mind of the subject; not all people have all characteristics. Practical biometric technologies must compromise on every point. Consequently, the challenge of biometric deployments is to develop robust systems to deal with the vagaries and variations of discernible characteristics of human beings.

All biometric systems verify claims (test hypotheses) regarding the source of a biometric pattern in the database. In application to computer network access control, the claim is a positive one, as in "I am the source of a biometric data record in the database," and will be accompanied by the submission of a "live" sample of the biometric pattern to be compared to the stored biometric record. This stored record is called the "biometric reference." Claims can be made specific, such as "I am the source of the biometric reference for subject A in the database," or can remain unspecified, requiring the computer to search the database for a matching reference. Claims need not involve a person's "real" name, so biometrics can be used anonymously. Implicit in the application of biometric recognition to computer network security is that the biometric data will be linked to a subject record, containing the network authorizations established at the time the biometric reference was created. Recognizing the person establishes a link to the authorizations and perhaps other data, such as a legal name, network usage records, and the like. In this chapter, we will call the subject data associated with an enrollment record an "identity" and will use the terms identity and *enrollment record* interchangeably. There is no need, however, for this identity to correspond to any identity for the same person in any other system. Biometrics is agnostic as to whom a person "really is" and cannot resolve the philosophical and moral issues of who a person "should be".

This approach to person recognition can be contrasted with the use of "something he knows" or "something he carries" in that biometrics links recognition to the person's body, not to knowledge or possessions, which are easily transferred (intentionally or unintentionally) to nonauthorized persons. Consequently, biometrics can be considered more secure than other forms of person recognition. But, in contrast to knowledge or possessions, biometric patterns cannot be replaced if compromised and are subject, like other forms of person recognition, to forgery and replay attacks (Geller et al. 1999; van der Putte and Keuning 2000; Lewis and Statham 2004; Matsumoto et al. 2002). Like "something he carries" biometrics will generally require specialized collection hardware at each point of service (keystroke and speaker recognition being possible exceptions). This is in contrast to "something he knows," which can be communicated to the network via an existing keyboard or numeric pad.

More general applications of biometrics also include verification of negative claims, such as "I am not the source of any biometric reference in the database." Social service and driver licensing systems make use of negative-claim biometric components to prevent multiple enrollments of a single individual. Whereas positive-claim systems can restrict each network identity to a single human subject, negative-claim systems can restrict each human subject to a single identity within the network, if that function is required.

Systems requiring a positive subject claim to a specific identity treat the biometric reference as an attribute of the enrollment record. These systems "verify" that the biometric reference in the claimed enrollment record matches the sample submitted by the subject and are called "verification" systems. Some systems, such as those for social service and driver licensing, verify a negative claim by a subject of having no identity record already in the database by treating the biometric pattern as a record identifier or pointer. These systems search the database of biometric pointers to find one matching the submitted sample and are called "identification" systems. However, the act of finding an identifier (or pointer) in a list of identifiers also verifies an unspecific claim of enrollment in the database, and not finding a pointer verifies a negative claim of no enrollment. Consequently, the differentiation between "identification" and "verification" systems is not always clear, and these terms are not mutually exclusive.

In the simplest systems, "verification" of a positive claim to a specific identity in the network might require the comparison of submitted samples to only the biometric references in the single claimed identity record. For example, a person might claim to be a specific, authorized network user. To prove this, she would type in an identity record identifier (perhaps a name or ID number), then place her finger on a glass platen of an electronic imaging device. The system would compare the sample fingerprint against the fingerprint reference in the claimed identity record. If the two were reasonably close, the system would conclude that the subject is indeed connected to the identity record and therefore should be afforded the rights and privileges associated with that identity.

Simple identification, done without a specific claim by the subject to an enrolled identity record, might require the comparison of the submitted biometric samples to all of the biometric references stored in the database. A personal computer log-on, for instance, can be implemented simply by the placement of the finger onto a scanner embedded in the keyboard. If the fingerprint matches any of those enrolled in the log-on database, that identity record is opened and its authorizations are granted.

Other "identification" applications, however, are much more complex. The State of California requires applicants for social service benefits to verify the negative claim of no previous enrollment in the system by submitting fingerprints from both index fingers to the Statewide Finger Imaging System. Depending on the specific automated search strategy, these fingerprints might be searched against the entire database of enrolled benefit recipients to verify that there are no matching fingerprints already in the system. If matching fingerprints are found, the enrollment record associated with those fingerprints is returned to the system administrator to confirm the rejection of the applicant's claim of no previous enrollment.

These are examples of the simplest systems. More advanced systems might use comparisons with multiple enrolled references for verification of linkage to a single, claimed identity or only a very limited number of comparisons when there is no claim to a specific enrolled reference. There is no dependable relationship between "verification" or "identification" and the number of comparisons that the system is required to make.

Network security systems generally use biometrics to verify positive subject claims to a specific or nonspecific identity in the database. These systems are commonly called “verification” systems regardless of the search strategy or architecture used. If a claim to an enrolled identity is verified, authorizations contained in the verified or identified enrollment record can then be applied with confidence to the requested activities, such as a computer log-on. Although hybrid systems are also possible, such as those that verify the negative claim that a subject does not already have an identity in the database at the time of enrollment and then verify in later encounters positive claims to an existing identity in the database, they are not currently widespread.

Biometric technologies are playing a growing role in computer network security today to connect persons to system authorizations through verification of claims of enrolled identity. The argument can be made that biometric measures more closely link the authentication process to the human network user than “what you have” or “what you know.” Biometric measures are not as easy to transfer, forget, or steal as PINs, passwords, and tokens, so they may increase the security level of systems using them. Biometrics can be combined with PINs and tokens into multifactor systems for added security should the PINs or tokens be stolen or compromised.

A SHORT HISTORY

The science of recognizing people based on physical measurements was invented by the French police clerk, Alphonse Bertillon, who began his work in the late 1870s (Beavan 2001; Cole 2001). The Bertillon system involved multiple measurements, including height, weight, the length and width of the head, width of the cheeks, and the lengths of the trunk, feet, ears, forearms, and middle and little fingers. Categorization of iris color and pattern was also included in the system. By the 1880s, the Bertillon system was in use in France to identify repeat criminal offenders. Use of the system in the United States for the identification of prisoners began shortly thereafter and continued into the 1920s.

Although research on fingerprinting by a British colonial magistrate in India, William Herschel, began in the late 1850s, knowledge of the technique did not become known in the Western world until the 1880s (Faulds 1880; Herschel, 1880) when it was popularized scientifically by Sir Francis Galton (1888) and in literature by Mark Twain (1893). Galton’s work also included the identification of persons from profile facial measurements.

By the mid-1920s, fingerprinting had completely replaced the Bertillon system within the U.S. Bureau of Investigation (later to become the Federal Bureau of Investigation). Research on new methods of human identification continued, however, in the scientific world. Handwriting analysis was recognized by 1929 (Osborn, 1929) and retinal identification was suggested in 1935 (Simon and Goldstein 1935).

These techniques were not automatic, however, so none of them meets the definition of “biometric authentication” being used in this chapter. Automatic techniques require automatic computation. Work in automatic speaker

recognition can be traced directly to experiments with analog filters conducted in the 1940s (Potter, Kopp, and Green 1947) and early 1950s (Chang, Pihl, and Essignmann 1951). With the increasing availability of industrial and government computers in the 1960s, speech (Pruzansky 1963) and fingerprint (Trauring 1963, On the automatic comparison) pattern recognition were among the very first applications in automatic signal processing. By 1963, a “wide, diverse market” for automatic fingerprint recognition was identified, with potential applications in “credit systems” and “industrial and military security systems” and for “personal locks” (Trauring 1963, Automatic comparison). Computerized facial recognition research followed (Bledsoe 1966; Goldstein, Harmon, and Lesk 1971). In the 1970s, the first operational fingerprint and hand geometry systems were fielded, results from formal biometric system tests were reported (Wegstein 1970), measures from multiple biometric devices were being combined (Messner et al. 1974; Fejfar 1978) and government testing guidelines were published (National Bureau of Standards 1977). In the 1980s, fingerprint scanners and speaker recognition systems were being connected to personal computers to control access to stored information. Based on a concept patented in the 1980s (Flom and Safir 1987), iris recognition systems became available in the mid-1990s (Daugman 1993; Siedlarz et al. 1995). Today there are over a dozen approaches used in commercially available systems, using hand and finger geometry, iris and fingerprint patterns, face images, voice and signature dynamics, computer keystroke, and hand vein patterns.

SYSTEM DESCRIPTION

Overview

Given the variety of applications and technologies, it might seem difficult to draw any generalizations about biometric systems. However, all such systems have many elements in common. Biometric samples are acquired from a person (the “subject”) by a sensor. During enrollment, these samples can be stored directly as the references for that subject. More commonly, the sensor output is sent to a processor, which extracts the distinctive but repeatable measures of the signal (the “features”), discarding all other components. If the subject is claiming no previous enrollment, the features can be compared to references from all enrolled subjects to verify this claim before a new identity record is created and the features are accepted as the reference “template” for the new record. Features might be processed further to produce a more complex statistical “model” to be stored as the subject reference instead of a template. An enrolled subject seeking access to a network will generally submit biometric samples to be compared to an enrolled reference in a claimed identity record linking the subject to network authorizations. The subject may identify the claimed identity record by entering a PIN, or through a token of some type, containing a pointer to the centrally stored, claimed record and its biometric reference. Alternatively, the claimed identity and its biometric reference might be stored on a token in the subject’s possession so that the subject supplies both

Figure 1: Example of a biometric system

a biometric sample to a sensor and a token from which the stored reference is read. Some highly distinctive biometric patterns, such as those of fingerprints or irises, may be submitted without the claim to a specific enrollment reference, thus necessitating a search of all references in a centralized database to find a “match” and thereby link to the appropriate subject authorizations.

Figure 1 illustrates this information flow, showing a general biometric system consisting of data collection, transmission, signal processing, reference storage, and decision subsystems. This diagram illustrates both enrollment and operation of systems designed for verifying specific or unspecific, positive or negative claims of enrollment. In the following sections, we will go through each of these subsystems in detail.

Data Collection

Biometric systems begin with the collection of a signal from a behavioral/biological characteristic. As data from a biometric sensor can be one-dimensional (speech), two-dimensional (fingerprint), or multidimensional (handwriting dynamics), we are not generally dealing with “images.” To simplify our vocabulary, we refer to the sensor output simply as “samples.”

Key to all systems is the underlying assumption that the signal from the biometric characteristic being observed is both distinctive between individuals and repeatable over time for the same individual. Therefore, it is desirable that there be as much variation between

individuals, and as little variation between multiple samples from the same individual, as possible. The challenges of controlling these sample variations begin in the data-collection subsystem.

The subject’s biometric characteristic must be observed by a sensor, such as a microphone, CCD (charge-coupled device)-based fingerprint scanning chip, or digital camera. In systems in which a subject seeks verification of a positive claim to an enrolled identity, the subject can cooperatively present the characteristic to the sensor. The act of presenting a biometric characteristic to a sensor introduces a behavioral component to every biometric method, as the subject must interact with the sensor in the collection environment. The output of the sensor is the combination of: (1) the biometric characteristic; (2) the way the characteristic is presented; and (3) the technical properties of the sensor. All measurements and decisions made by the system will be based on this sensor output. Both the repeatability and the distinctiveness of the measurement are negatively impacted by changes in any of these three factors. We must emphasize the importance of good ergonomic design on item 2, allowing users of the system to easily and quickly present biometric characteristics. If a system is to exchange data with other systems, the presentation constraints and sensor properties must be standardized (International Standards Organization 2005, Parts 2, 4, 5, and 6) to ensure that biometric characteristics collected with one system will match those collected on the same individual by another system.

Transmission

Some biometric systems collect samples at one location but process them at another. If a great amount of data is involved, data compression may be required to conserve transmission bandwidth. Systems storing unprocessed biometric samples as the references do so in a compressed format. Figure 1 shows compression and transmission occurring before signal processing or sample storage. The transmitted or stored compressed data must be expanded before further use. The process of compression and expansion generally causes quality loss in the restored sample, with loss increasing with higher compression ratios. An interesting area of research is in finding, for a given biometric technique, compression methods with minimum negative impact on the subsequent signal-processing activities. Interestingly, limited compression has been observed, in many cases, to improve the performance of the pattern-recognition software (Watson and Wilson 2005), as information loss in the original signal is generally in the less repeatable high-frequency components.

Signal Processing

The biometrics signal-processing subsystem is composed of four modules: segmentation, feature extraction, quality control, and pattern matching. The segmentation module must determine whether any biometric signals exist in the received data stream (signal detection) and, if so, extract the signal from the surrounding noise. If the segmentation module fails to properly detect or extract a biometric signal, we say that a “failure-to-acquire” has occurred.

The feature-extraction module must process the signal in some way to preserve or enhance the between-individual variation (distinctiveness) while minimizing the within-individual variation (nonrepeatability). The output of this module is numbers that, although called biometric “features,” may not have direct biological or behavioral interpretation. For example, the numerical values developed by a facial recognition system do not indicate the width of the lips, length of the nose, or the distance between the eyes and the mouth, but rather represent the face in a more abstract, mathematically based way, such as by “decomposing” the face into “basis” faces. In this process, a preset collection (perhaps 128) of generic “basis” faces can be combined with determined intensities to approximate the face being decomposed. The values of these intensities are the numbers by which the face will be recognized.

The quality-control module must do a statistical “sanity check” on the extracted features to make sure they are not outside population statistical norms. If the sanity check is not successfully passed, the system may be able to alert the subject to resubmit the biometric pattern. If the biometric system is ultimately unable to produce an acceptable feature set from a subject, a “failure-to-enroll” or a “failure-to-acquire” will have occurred. Failure-to-enroll/acquire may be due to failure of the segmentation algorithm, in which case no feature set will be produced. The quality-control module might even impact the decision process, directing the decision subsystem to adopt higher requirements for matching a poor-quality input sample, for instance.

The pattern-matching module compares sample feature data with previously enrolled feature data (“templates”) or feature data models (such as neural network or Gaussian mixture models) from the database and produces a numerical “comparison score.” When both the reference and features are vectors, the comparison score may be as simple as a Euclidean distance. In more complex systems, statistical measures, such as likelihood ratios, might be used instead. Some pattern-matching modules may even direct the adaptive recomputation of features from the input data to see whether better matches might be made through small adjustments to the input data. Regardless of what pattern-matching technique is used, references and features from samples will never exactly match because of the repeatability issues already discussed. Consequently, the comparison scores determined by the pattern-matching module will have to be interpreted by the decision subsystem.

or feature data models (such as neural network or Gaussian mixture models) from the database and produces a numerical “comparison score.” When both the reference and features are vectors, the comparison score may be as simple as a Euclidean distance. In more complex systems, statistical measures, such as likelihood ratios, might be used instead. Some pattern-matching modules may even direct the adaptive recomputation of features from the input data to see whether better matches might be made through small adjustments to the input data. Regardless of what pattern-matching technique is used, references and features from samples will never exactly match because of the repeatability issues already discussed. Consequently, the comparison scores determined by the pattern-matching module will have to be interpreted by the decision subsystem.

Decision

The decision subsystem is considered separately from the pattern-matching module. The decision subsystem might make a simple “match” or “no match” determination by comparing the output score from the pattern-matching module against a predetermined threshold value. A subject claim of an identity within a system will be accepted if a match is determined. A subject claim of no identity within a system will be rejected if a match is determined. Consequently, relating “match” and “no match” decisions to claim “acceptance” or “rejection” will depend on the claim being made. System policy may require that the ultimate “acceptance” or “rejection” of a subject’s claim be based on multiple “match/no match” decisions from multiple measures or from some dynamically determined, subject-dependent or measure-dependent decision criterion. For instance, common decision policies will accept a subject claim to an identity record if a match occurs in any of three attempts or against any one of several stored references.

The decision module might also direct operations to the stored database, storing features as reference templates during enrollment, updating references in the database after a successful transaction, calling up additional references for comparison in the pattern-matching module, or directing a database search.

Because input samples and stored references will never exactly match, the decision modules will make mistakes—wrongly rejecting a correctly claimed identity of an enrolled subject or wrongly accepting the identity claim of an impostor. Thus, there are two types of errors: false rejection and false acceptance. In systems verifying positive subject claims to identity, these errors can be traded off against one another to a limited extent: decreasing false rejections at the cost of increased false acceptances and vice versa. In practice, however, inherent within-individual variation (nonrepeatability) limits the extent to which false rejections can be reduced, short of accepting all comparisons. The decision policies regarding match/no match and the accept/reject criteria are specific to the operational and security requirements of the system and reflect the ultimate cost and likelihood of errors of both types. These errors can be reduced if the sample size is increased—that is, a number of repeated data inputs are taken from the subject.

Because of the inevitability of false rejections, all biometric systems must have exception-handling mechanisms in place. If exception-handling mechanisms are not as strong as the basic biometric security system, vulnerability will result. High numbers of falsely rejected transactions may overload even strong exception-handling mechanisms and lower the responsiveness of system management to potential attacks on the system. Consequently, a high false rejection rate can lead not only to subject inconvenience and operational delays, but to a compromise in system security as well.

In a system assessing a positive claim, the false acceptance rate measures the percentage of “zero effort” impostor transactions that result in access to the system. The false acceptance rate should never be confused with the probability that a successful transaction is actually fraudulent. This latter probability depends on both the false acceptance rate and the percentage of all transaction attempts that are actually by impostors. Depending on the application and how alarms are handled, even a 20 percent false acceptance rate (which indicates an 80 percent probability of intercepting an impostor) may be low enough to decrease the frequency of attacks on the biometric system to the point at which there are no successful impostor transactions. Truly determined fraudulent persons might find other entry points, including the exception-handling mechanism, more appealing than the biometric portal.

Consequently, the security level provided by a biometric system might be as sensitive to the false rejection rate as it is to the false acceptance rate. Sound practice would indicate that we do not rely only on a single biometric safeguard to catch every impostor; do not place extreme emphasis on attaining near-zero false acceptance rates, and continue to couple biometrics with other methods, such as PINs and passwords.

Reference Storage

The remaining subsystem to be considered is that of reference storage. Submitted samples, extracted features, or the feature-generated model of each enrolled subject is stored in an identity record in the database for future comparison by the pattern matcher to incoming samples. Systems for verifying negative claims of identity require a centralized database (or the equivalent—linked decentralized databases) of all enrolled references to verify a claim that a person does not have an identity in the system. Such systems generally return the records of any enrollments found, and so are called “identification” systems, as previously discussed. Large-scale identification systems generally partition the database using factors such as gender or age so that not all centrally stored references need be examined to establish that a person is not in the database. Such systems are sometimes loosely called “one-to-N” or “one-to-many” to indicate that a submitted sample must be compared to multiple identity records.

For systems only verifying positive claims to a specific identity, the database of references may be distributed on magnetic stripe, optically read, or smart cards carried by each enrolled subject; no centralized database need exist. Such positive verification systems are sometimes loosely called “one-to-one,” to indicate that biometric samples

might be compared to the references of only the single claimed identity. However, verification systems based on likelihood-estimation techniques compare samples not only to the claimed references, but also to the references of other subjects or to “background models,” and therefore might not be strictly “one-to-one” with regard to the total number of comparisons required.

Although distributed storage is possible, positive claim verification systems might use a centralized, encrypted database to prevent creation of counterfeit cards or to re-issue lost cards without re-collecting the biometric data.

The original biometric measurement, such as a fingerprint pattern, is generally not reconstructable from its stored reference, unless that reference is in the form of a compressed sample. However, if access can be had to unencrypted references of any type, it is quite possible for a knowledgeable hacker in possession of an identical system to construct an artifact capable of matching the compromised reference. Unlike PINs and passwords, however, biometric data cannot be changed at the request of the subject. For this reason, biometric references must always be protected as sensitive data and will generally require encryption, even when stored on user-controlled cards. Several forms of encryption specific to biometric data have been proposed in the literature (Kumar, Khosla, and Savvides 2004; Ratha, Connell, and Bolle 2001; Hao, Anderson, and Daugman 2005). The decision to maintain a centralized reference database for verification applications should be done with an assessment of the privacy and security risks should the database be compromised.

Table 1 shows some examples of unencrypted template sizes for various biometric devices.

PERFORMANCE TESTING

Biometric devices and systems might be tested in many different ways. Types of testing include:

- Technical performance
- Reliability, availability, and maintainability (RAM)
- Vulnerability
- Security
- User acceptance
- Human factors
- Cost/benefit
- Privacy regulation compliance

Table 1: Biometric Template Sizes

Device	Size in Bytes
Fingerprint	200–1000
Speaker	100–6000
Finger geometry	14–48
Hand geometry	9–72
Face	100–3500
Iris	512

Technical performance has been the most common form of testing in the past four decades. Technical tests are generally conducted with the goal of predicting system performance with a target population in a target environment, but historically, extrapolation of results from a test environment to the “real world” has been difficult. This may be largely due to the variability of human performance between the lab and the field. Ultimately “technical performance” is a measure of how well people perform when interacting with these technologies.

Technical tests can be either “closed-set” or “open-set”. A “closed-set” test assumes that all subjects are enrolled in the system and does not acknowledge the existence of impostors. A closed-set test returns the rank of the true comparison when an input sample is compared to all of the enrolled patterns. Closed-set tests measure the probability that the true pattern was found at rank k or better in the search against the database of size N . In any test, the rank k probability is dependent on the database size, decreasing as the database size (i.e., number of references) increases.

An “open-set” test does not require that all input samples be represented by a reference in the enrolled database and measures all comparison scores against a score threshold. An open-set test returns, as a function of the threshold, the probability of either missing a true comparison (the false nonmatch rate) or matching on a wrong comparison (the false match rate). Open-set measures are independent of the size of the database searched, converging to the correct estimator as the test size increases. Examples of both open-set and closed-set tests are found in the literature, but since most applications must acknowledge the potential for impostors, open-set results are of greater practical value to the system designer or analyst.

To make test results more predictive of real-world performance, testing “best practices” (Mansfield and Wayman 2002) and standards (International Standards Organization 2006) have been developed. Metrics generally collected in open-set technical tests are: failure-to-enroll, failure-to-acquire, false nonmatch, false match, false acceptance, false rejection, and throughput rates. Failure-to-enroll rate is determined as the percentage of all persons presenting themselves to the system in “good faith” for enrollment who are unable to do so because of system or human failure. Failure-to-acquire rate is determined as the percentage of “good faith” presentations by all enrolled persons who are not acknowledged by the system. The false nonmatch rate is the probability that a single sample from a randomly chosen, “good faith” subject will not match his own reference. The false match rate is the probability that a single biometric sample from a randomly chosen subject (acting in “good faith” to match her own reference) will be wrongly matched to a single reference of a different, randomly chosen subject.

In biometric systems in which subjects make a positive claim to linkage with an identity, such as access control to computer networks, the false rejection rate is the percentage of all subjects whose claim to identity is not accepted by the system after some number of attempts. This will include failed enrollments and failed acquisitions, as well as false nonmatches against the subject’s stored reference. The false acceptance rate for positive claim systems is the rate at which “zero-effort” impostors making no

attempt at impersonation are incorrectly matched, after some number of attempts, to a single, randomly chosen false identity. Because false acceptance/rejection (as well as false match/nonmatch rates) are competing measures, they can be displayed together on a “decision error trade-off” (DET) curve.

The throughput rate is the number of persons processed by the system per minute, and includes both the human-machine interaction time and the computational processing time of the system. Ultimately, the throughput and error rates will be dependent on the interaction of the humans with the technology. This implies that not only will good ergonomic design be of great importance, but so will subject attitudes and perceptions.

Types of Technical Tests

Three types of technical tests have been described: technology, scenario, and operational (Phillips et al. 2000; International Standards Organization 2006; Wayman et al. 2005).

Technology Test

The goal of a technology test is to compare competing algorithms from a single technology, such as fingerprinting, against a standardized database collected with a “universal” sensor. There are competitive, government-sponsored technology tests in speaker verification (Martin, Przybocki, and Campbell 2005; NIST 2006), facial recognition (Phillips et al. 2005), and fingerprinting (Maio et al. 2002; Wilson et al. 2004; Watson et al. 2005; Capelli et al. 2006).

Scenario Test

Whereas the goal of technology testing is to assess the algorithm, the goal of scenario testing is to assess the performance of the subjects as they interact with the complete system in an environment that models a “real-world” application. Each system tested will have its own acquisition sensor and so will receive slightly different data. Scenario testing has been performed by a number of groups, but few results have been published openly (Fejfar and Myers 1977; Rodriguez, Bouchier, and Ruehie 1993; Bouchier, Ahrens, and Wells 1996; Mansfield et al. 2001). Scenarios may differ with regard to variables such as the level of subject habituation, cooperation and supervision, the physical environment of enrollment and collection (i.e., indoor/outdoor), whether subjects are from the general or more restricted populations, and whether references are collected on the same system or collected elsewhere and imported.

Operational Test

The goal of operational testing is to determine the performance of a target population in a specific application environment with a complete biometric system. In general, operational test results will not be repeatable because of unknown and undocumented differences between operational environments. Further, “ground truth” (i.e., who was actually presenting a “good faith” biometric measure) will be difficult to ascertain. Because of the sensitivity of information regarding error rates of operational systems,

few results have been reported in the open literature (Wayman 2000).

Regardless of the type of test, all biometric authentication techniques require human interaction with a data-collection device, either standing alone (as in technology testing) or as part of an automatic system (as in scenario and operational testing). Consequently, humans are a key component in all system assessments. Error, failure-to-enroll/acquire, and throughput rates are determined by the human interaction, which in turn depends on the specifics of the collection environment. Therefore, little can be said beyond the context of the test about the performance of biometric systems, or more accurately, about the performance of the humans as they interact with biometrics systems.

The National Physical Lab Tests

A study by the U.K. National Physical Laboratory (Mansfield et al. 2001) looked at eight commercially available biometric products in a scenario test designed to emulate access control to computer networks or physical spaces by scientific professionals in a quiet office environment. A more detailed description of the products, test environment and volunteer population is available in the original report.

The false accept/false reject DET under a "three-tries" decision policy for this test is shown in Figure 2. The false rejection rate includes failure-to-enroll/acquire rates in its calculation.

Figure 2 allows estimation of the false rejection rate for each of the tested products for any required false acceptance rate, but only for this test environment and this set of test subjects. The figure does not show the decision thresholds required to attain those false acceptance rates. The tested products may not be representative of the technology in general and it is not possible to extrapolate these results to any other application environment or set of test subjects. For example, the figure shows that it is possible for National Physical Laboratory subjects using hand geometry to attain a 1 percent false rejection rate at a 0.1 percent false acceptance rate in this environment. A failure-to-enroll was considered as a "false rejection" in the computation of this figure. These

results relate to the average error rates over all subjects. Individuals may have error rates considerably above or below the averages.

It is also important to note that the National Physical Laboratory results do not tell us about the subject error rates with technologies such as PINs and tokens, generally thought to be competitors of biometrics. Determining the strength of biometrics relative to the other mechanisms for personal identification is an unresolved research issue.

The National Physical Laboratory study also established the access control transaction times for the above subjects with the various biometric devices in this office environment as shown in Table 2.

In Table 2, the term "PIN?" indicates whether the transaction time included the manual entry of a four-digit identification number by the subject. These times referred only to the use of the biometric device and did not include actually accessing a restricted area.

BIOMETRICS AND COMPUTER NETWORK SECURITY

Biometrics can have an important role in computer network security, being much more closely linked to an individual and more difficult to forget, give away, or lose than a token, a PIN, or a password. Use of biometrics can provide additional evidence that an authorization credential is being presented by the person to whom it was issued. However, biometric technologies do not represent a silver bullet, eliminating PINs, passwords, and tokens while resolving all security issues.

In devising a system architecture for verifying a positive claim to identity, we must decide whether each biometric reference will be carried by the persons themselves on a token, or whether all references will be stored centrally in a database linked to the point of service by a communications system. The former approach has positive implications for privacy (Kent and Millett 2003), but will require some form of key, such as a PIN or a password, to unlock the biometric measure that will be encrypted on the token. Consequently, all the general issues regarding data security on tokens still exist.

Figure 2: Detection error trade-off curve: best of three attempts

Table 2: Transaction Times in Office Environment

Device	Transaction Time (seconds)			PIN?
	Mean	Median	Minimum	
Face	15	14	10	No
Fingerprint—optical	9	8	2	No
Fingerprint—chip	19	15	9	No
Hand	10	8	4	Yes
Iris	12	10	4	Yes
Vein	18	16	11	Yes
Speaker	12	11	10	No

If biometric references are stored centrally, several questions arise:

1. Will the biometric sample be sent to the central system, or will the central system pass the reference to the point of service for processing? In either case, some strong form of encryption will be required to protect the data during transmission.
2. If the input data is sent from the point of service to the central site, will it be in raw form or processed into features? If processed into features prior to transmission, computational power and knowledge of the feature extraction algorithm will be required at each point of service but transmission bandwidth will be reduced.
3. How will the encrypted data be unencrypted when necessary for comparison?
4. How will the subject judge the point of service to be legitimate and not to be storing the biometric data after transmission?

Although these problems are not insurmountable, they demonstrate that use of biometrics does not eliminate the usual security issues.

It has been well known since the 1970s that biometric devices can be fooled by forgeries (Lummis and Rosenberg, 1972; Raphael and Young 1974; National Bureau of Standards 1977). In a system for verifying positive claims of identity, “spoofing” is the use of a forgery of another person’s biometric measures. In a system for verifying a negative claim, spoofing is an attempt to disguise one’s own biometric measure. Forging biometric measures of another person is more difficult than disguising one’s own measures, but is quite possible nonetheless. Several studies (Blackburn et al. 2000; van der Putte and Keuning 2000; Matsumoto et al. 2002; Thalheim, Krissler, and Ziegler 2002) discuss ways by which facial, fingerprint, and iris biometrics can be forged. Speaker recognition systems can make forgery difficult by requesting the subject to say numbers randomly chosen by computer. However, the current state of technology does not provide reliable “liveness testing” to ensure that the biometric measure is both from a living person *and* not a forgery.

The use of biometrics does not reduce the need to fully scrutinize all applicants for authorizations. A biometric system can neither verify the external truth of the enrolled identity itself nor establish the link automatically to an identity record with complete certainty. Determining an individual’s “true” identity, if required, is done at the time of enrollment through trusted external documentation, such as a birth certificate or driver’s license. The biometric measures link the individual to an enrolled identity and associated authorizations that are only as valid as the original determination process.

Not all systems, however, have a requirement to know an individual’s “true” name or identity. Biometric measures can be used as anonymous and pseudo-anonymous identifiers, and consequently, have intriguing potential for privacy enhancement of authorization systems.

All biometric measures may change over time, because of aging, injury, or disease. Therefore, reenrollment may be required. If “true” identity or continuity of identity is required by the system, reenrollment must necessitate presentation of trusted external documentation. Both enrollment and reenrollment also require the physical presence of the enrolling person before the enrolling authority. Otherwise, there is no way to determine that the enrolled biometric measure came from the body of the person presenting it.

EXAMPLE APPLICATIONS

San Jose State University

San Jose State University has been using hand geometry readers for around-the-clock controlled, secure access to the Computer and Telecommunications Center since 1993. About 125 employees are enrolled in the system and log a combined 500 entrance events each day at the three entrances. The system records all events on a central PC, allowing management to audit after-hours access to the Center.

Employees enter a four-digit PIN into the system and place their right hand down on a reflective platen. Infrared light reflects vertically off the platen, but not the skin, allowing a “shadow” of the hand without the skin texture information to be imaged. In addition, a mirror reflects light horizontally across the top of the hand, supplying

a second two-dimensional shadow of the side of the hand. Both of these two-dimensional images are reduced using image-processing techniques to a 9-byte feature vector, the values of which cannot be directly related to finger lengths, widths, or other anatomical measures. If the sample is "close enough" in Euclidean distance to the 9-byte template stored at enrollment, the door strike opens and access is permitted. Upon successful use, the system automatically updates the stored template by averaging in the newly acquired sample. The threshold used to determine "close enough" can be set individually, if necessary, to accommodate anyone having unusual difficulty using the system. The entire access process takes just a few seconds and the false rejection of daily, habituated system users is exceedingly rare.

Impostors would need both a valid PIN and the correct hand shape to gain access to the system. PIN guessing can be prevented by locking the system or sounding an alarm after some number of consecutive access failures.

The hand readers at each door cost about \$1,500 in 2006. Some additional items, such as electrically activated door strikes, cabling, and "request to exit" switches were purchased and installed, as well. The door strikes are controlled and powered directly from the hand reader unit. Although the units can stand alone, a central PC is used for event logging and for networking multiple units into a single reference database. University management has been quite pleased with the cost, efficiency, and security of the system.

We can classify this as an application to verify a positive claim of identity, with trained, habituated subjects in an unsupervised office environment. The system is used only by employees of the Computer and Telecommunications Center, so is not a public application. It serves as a good cost, performance, and procedure model only for proposed applications with these same characteristics.

Purdue Employees Federal Credit Union

Since 1997, Purdue Employees Federal Credit Union (PEFCU) in West Lafayette, Indiana, has been using fingerprint verification to replace PINs at five automatic teller machine (ATM) kiosks. About 11,500 customers (20 percent of the PEFCU membership) are enrolled in the system, generating about 28,000 biometrically enabled transactions per month. Customers electing to use fingerprinting can enroll in the system at the central office by presenting any two fingers to an optical scanner. Customers with poor fingerprints due to age or occupation, and customers not wishing to participate, can continue to use traditional PINs at all PEFCU ATMs.

The scanner takes a digital image of the fingerprint, which is converted into "minutiae features," a numerical structure based on the patterns in the fingerprint ridges. These features, but not the original fingerprint image, are stored in a central database. After enrollment, customers can withdraw or deposit cash or apply for loans presenting their ATM card with either enrolled fingerprint to the kiosk scanner. No PIN entry is required. To guide customers in the proper placement of the finger, a display screen on the kiosk shows the customer the image of the presented fingerprint and an image of an ideally placed

finger. The features extracted from the presented fingerprint are compared to those in the reference stored in the central database under the entered customer name. Close similarity between the stored and presented features verifies that the customer is the source of the claimed enrollment record and is, therefore, the authorized ATM card holder.

The fingerprinting technology is estimated to represent only a small fraction of the total \$70,000 cost of the ATM kiosk. No case of fraud owing to misuse of the fingerprinting system has ever been reported. Incidence of fraud originating from fingerprint-equipped ATMs is currently less than 5 percent of the fraud rate on other ATMs operated by PEFCU. The credit union is currently expanding the fingerprint system to traditional teller lines to eliminate the need for enrolled customers to present photo identification when making cash withdrawals.

We can classify this use by PEFCU as an application to verify a positive claim of identity, with habituated and nonhabituated customers in an unsupervised indoor or outdoor environment. The system is used by a wide cross section of credit union customers, so can be called a public application. Consequently, we would expect the PEFCU application to be more challenging than the San Jose State University Computer Center application, with its more controlled population and environment.

BIOMETRICS AND PRIVACY

The concept of "privacy" is highly culturally dependent. Legal definitions vary from country to country and, in the United States, even from state to state (Alderman and Kennedy 1995). A classic definition is the intrinsic "right to be let alone" (Warren and Brandeis 1890), but more modern definitions include informational privacy: the right of individuals "to determine for themselves when, how and to what extent information about them is communicated to others" (Westin 1967). Both types of privacy can be impacted positively or negatively by biometric technology.

Intrinsic (or Physical) Privacy

Some people see the use of biometric devices as an intrusion on intrinsic privacy. Touching a publicly used biometric device, such as a fingerprint or hand geometry reader, may seem physically intrusive, even though there is no evidence that disease can spread any more easily by these devices than by door handles. People may also object to being asked to look into cameras or to stand still while giving an iris or facial image.

Not all biometric methods require physical contact. A biometric application that replaced the use of a keypad with the imaging of an iris, for instance, might be seen as an enhancement of physical privacy.

If biometrics is used to limit access to private spaces, then biometrics can be more enhancing to intrinsic privacy than other forms of access control, such as keys, which are not as closely linked to the holder.

There are people who object to the use of biometrics on religious grounds: Some Muslim women object to displaying their face to a camera and some Christians object to hand biometrics as the Biblical "the sign of the

beast." In response, it has been noted (Siedlarz 1998) that a theistic interpretation would more properly consider biometric patterns to be marks given by God.

It can be argued (Locke 1690; Baker 2000) that a physical body is not identical to the person that inhabits it. Whereas PINs and passwords identify persons, biometrics identifies the body. Some people are uncomfortable with biometrics because of this connection to the physical manifestation of human identity, the possibility of non-consensual collection, and the impossibility of changing biometric measures if stolen. Biometric measures could allow linking of the various "persons" or psychological identities that each of us choose to manifest in our separate dealings within our social structures. Biometrics, if universally collected without adequate controls, could aid in linking employment records to health history and church membership, for example. This leads us to the concept of "informational privacy."

Informational Privacy

With notably minor qualifications, biometric features contain no personal information whatsoever about the subject. This includes no information about health status, age, nationality, ethnicity, or gender. Consequently, this also limits the power of biometrics to prevent underage access to pornography on the Internet or to detect voting registration by noncitizens.

No single biometric measure has been demonstrated to be distinctive or repeatable enough to allow the selection of a single person out of a very large database. However, when aggregated with other data, such as name, telephone area code, or other even weakly identifying attributes, biometric measures can lead to *unique* identification within a large population. For this reason, databases of biometric information must be treated as personally identifiable information and protected accordingly.

Biometrics can be directly used to enhance informational privacy. Use to control access to and promote accountability with databases containing personal and personally identifiable data can enhance informational privacy. The use of biometric measures, in place of name or social security number, to make personal data anonymous, enhances privacy.

SUGGESTED RULES FOR SECURE USE OF BIOMETRICS

From what has been discussed thus far, we can develop some reasonable rules for the use of biometrics for logical and physical access control, and similar applications.

1. Never participate in a biometric system that allows either remote enrollment or reenrollment. Such systems have no way of connecting a subject with the enrolled biometric data, so the purpose of using biometrics to connect the subject more closely to the authentication mechanism is lost.
2. Biometric measures can reveal your "real" identity only if they are linked at enrollment to your name, social security number, or other closely identifying

information. Without that linkage, your biometric measures are anonymous.

3. Remember that biometric measures cannot be reissued if stolen or sold. Do not enroll in a biometric system unless you have complete trust in the system administration.
4. All biometric access control systems must have exception-handling mechanisms for those that either cannot enroll or cannot reliably use the system. If you are uncomfortable with enrolling in a biometric system for verifying positive claims of identity, insist on routinely using the exception-handling mechanism instead.
5. The most privacy-enhancing biometric systems are those in which each subject controls his/her own reference.
6. Because biometric measures are not perfectly repeatable, are not completely distinctive, and require specialized data collection hardware, biometric systems are not useful for tracking people within large populations. Anyone who really wants to physically track the movements of a person in a large population will use credit card or phone records or cell phone emanations instead. But over a small population, biometric measures are distinctive and repeatable enough to provide accountability for activities such as accessing stored information. Consequently, the technology itself should not be feared. In the proper applications, biometrics can be used as a strongly privacy-enhancing technology.

CONCLUSION

Automated methods for human identification have a history predating the digital computer age. For decades, mass adoption of biometric technologies has appeared to be just a few years away (Raphael and Young 1974), yet even today, difficulties remain in establishing a strong business case, in motivating consumer demand, and in creating a single system usable by all sizes and shapes of persons. Nonetheless, the biometric industry has grown at a steady pace as consumers, industry, and government have found appropriate applications for these technologies, particularly in the area of computer security. Although the privacy implications continue to be debated, biometrics can be used in privacy-enhancing applications. At the current level of development, biometric technologies seem to be a reasonable alternative to PINs and passwords in some applications associated with computer network security.

GLOSSARY

Biometric Reference: Stored biometric data used as a pointer to, or an attribute of, an enrollment record for an individual. Data can be in the form of a raw sample, a template consisting of mathematical features extracted from a sample(s), or as a model based on extracted features.

Biometrics: The automatic recognition of individuals based on distinguishing biological and behavioral traits.

Comparison Score: A measure of similarity or dissimilarity between a presented sample and a stored biometric reference.

Decision: A determination of probable validity of an individual's claim to an identity or no identity in the system.

Enrollment: The presentation of an individual to an biometric system for the first time, creating an identity record within the system, and collecting biometric samples for the creation of a biometric reference to that identity.

Failure-to-Acquire Rate: The percentage of transactions for which the system cannot obtain a usable biometric sample.

Failure-to-Enroll Rate: The percentage of a potential system's users for which the system cannot create a usable biometric reference.

False Acceptance rate (FAR): The expected proportion of transactions with wrongful claims of identity (in a positive ID system) or nonidentity (in a negative ID system) that are incorrectly confirmed. In applications to verify positive claims, the FAR will depend on the false match rate and the system policy specifying how many attempts will be allowed to prove the claimed identity. In negative identification systems, the FAR may include the failure-to-acquire rate and the false nonmatch rate.

False Match Rate (FMR): The false match rate is the expected probability that a sample acquired from an individual will be falsely declared to match to a single reference from a different, randomly selected individual.

False Nonmatch Rate (FNMR): The false nonmatch rate is the expected probability that an acquired sample will be falsely declared not to match a reference from the same individual.

False Rejection Rate (FRR): The expected proportion of transactions with truthful claims of identity (in a positive ID system) or nonidentity (in a negative ID system) that are incorrectly denied. In positive identification systems, the FRR will include the failure-to-enroll and the failure-to-acquire rates, as well as the false nonmatch rate.

Features: A mathematical representation of the information extracted from the presented sample by the signal processing subsystem that will be used to construct or compare against biometric references. Biometric features generally have no direct anatomical meaning.

Identifier: An identity pointer, such as a biometric reference, a PIN (personal identification number) or a name.

Identity: An information record about a person, perhaps including attributes or authorizations, or other pointers, such as names or identifying numbers.

Models: Biometric references derived through further mathematical processing of biometric features, perhaps indicative of the feature-generating process.

Negative Claim of Identity: The claim that an individual is neither known to nor enrolled in the system. As an example, social service systems open only to those not already enrolled require all applicants to make negative claims to any existing identity in the system.

Positive Claim of Identity: The claim that an individual is enrolled in or known to the system. A specific positive claim of identity will be accompanied by an identifier in the form of a name, PIN, or identification number. Common access control systems are an example. A non-specific positive claim of identity will not require any identifier be given other than the biometric sample. "PIN-less" verification systems are an example.

Sample: A biometric signal derived from an individual and captured by the data collection subsystem. (Voice signals, fingerprints, and face images are samples)

Template: A stored reference consisting of features extracted from biometric samples.

Transaction: An attempt by an individual to prove a claim of identity or nonidentity by consecutively submitting one or more samples, as allowed by the system policy.

Verification: Proving as truthful an individual's claim to an identity in the system.

Zero-Effort Impostor: A fraudulent or opportunistic individual who submits their own biometric measure without alteration in an attempt to make a positive claim to another, randomly chosen identity.

INTRODUCTION

When an organization or individual links to the Internet, a two-way access point out of and in to their information systems is created. To prevent unauthorized activities between the Internet and the private network, a specialized hardware, software, or software-hardware combination known as a firewall is often deployed.

Overall Firewall Functionality

Firewall software often runs on a dedicated server between the Internet and the protected network. Firmware-based firewalls and single-purpose dedicated firewall appliances are situated in a similar location on a network and provide similar functionality to the software-based firewall. All network traffic entering the firewall is examined, and possibly filtered, to ensure that only authorized activities take place. This process may be limited to verifying authorized access to requested files or services, or it may delve more deeply into content, location, time, date, day of week, participants, or other criteria of interest. Firewalls

usually provide a layer of isolation between the inside, sometimes referred to as the “clean” network, and the outside or “dirty” network. They are also used, although less frequently, to separate multiple subnetworks so as to control interactions between them. Figure 1 illustrates a typical installation of a firewall in a perimeter security configuration.

A common underlying assumption in such a design scenario is that all of the threats come from outside the network or from the Internet, but many modern firewalls provide protection against insiders acting inappropriately and against accidental harm that could result from internal configuration errors, viruses, or experimental implementations. Research consistently indicates that 70 to 80 percent of malicious activity originates from insiders who would normally have access to systems both inside and outside the firewall. In addition, outside threats may be able to circumvent the firewall entirely if dial-up modem access remains uncontrolled or unmonitored, if wireless LANs (local area networks) or similar wireless technology is used, or if other methods can be used to

Figure 1: Typical installation of a firewall in a perimeter security configuration

co-opt an insider, to subvert the integrity of systems within the firewall, or to otherwise bypass the firewall as a route for communications. Incorrectly implemented firewalls can exacerbate this situation by creating new, and sometimes undetected, security holes or by creating such an impediment to legitimate uses that insiders subvert its mechanisms intentionally. It is often said that an incorrectly configured and maintained firewall is worse than no firewall at all because it gives a false sense of security.

Advantages

- When properly configured and monitored, firewalls can be an effective way to protect network and information resources.
- Firewalls are often used to reduce the costs associated with protecting larger numbers of computers that are located inside it.
- Firewalls provide a control point that can be used for other protective purposes.

Disadvantages

- Firewalls can be complex devices with complicated rule sets.
- Firewalls must be configured, managed, and monitored by properly trained personnel.
- A misconfigured firewall gives the illusion of security.
- Even a properly configured firewall is not sufficient or complete as a perimeter security solution. A total security solution typically also includes intrusion-detection/prevention systems, vulnerability assessment technology, and antivirus technology. Eighty percent of successful network attacks either penetrate or avoid firewall security.
- The processing of packets by a firewall inevitably introduces latency that, in some cases, can be significant.
- Firewalls often interfere with network applications that may expect direct connections to end user workstations such as voice over Internet protocol (VoIP) phones and VPNs (virtual private networks) as well as some collaborative tools such as instant messenger and video and audio conferencing software.
- The level to which firewalls inspect the data contained with packets varies widely. While some firewalls filter

packets based only on source and destination addresses, other firewalls perform much more comprehensive packet inspection on the contents of those packets.

- Firewalls cannot prevent vulnerabilities introduced directly at client computers, such as malicious code, e-mail attacks, and Web-based Trojans. Trojan programs can then launch attacks within the internal network, undetected by the perimeter-based firewall.

FIREWALL FUNCTIONALITY

Background

Network communication between computers, whether or not that communication is through a firewall, is most often organized into layers according to the OSI (open systems interconnect) model. Figure 2 illustrates basic firewall functionality and technology categories in terms of the OSI model.

Firewalls were initially introduced as application-level programs running over standard operating systems. As a result, these firewall programs were easily bypassed by directly attacking the vulnerabilities of the underlying TCP/IP (or network protocol) stack and native operating system over which these firewall applications were executing. Such operating systems were often default installations and were sometimes referred to as nonhardened operating systems. Firewall application software conforming to this type of configuration is sometimes referred to as first-generation firewalls.

Today, most firewalls use hardened operating systems and are run as single programs on a dedicated computing device or hardware firewall appliance. As a result, it is more difficult to attack firewalls through the underlying vulnerabilities of operating systems and network protocols. Firewalls conforming to this architecture are sometimes referred to as second-generation firewalls.

Firewalls basically act as filters. They either allow or disallow a given packet based on rules contained in a filter table. At the highest level, filtering is either positive or negative. Positive filters allow traffic to pass through the firewall if those packets meet the criteria listed in the filter table and block all traffic that does not. Negative filters prevent any traffic that meets criteria on filter tables from passing through the firewall and allows all traffic to pass that does not. Firewall rules are processed in a serial

OSI Model Layer	Firewall Functionality	Firewall Technology	
7—Application	Application-level proxies, forward and reverse proxies	Proxy servers	Switched firewalls Air gap technology
6—Presentation		Firewall	
5—Session	Stateful firewall	Appliances	
4—Transport: TCP/UDP	Port filtering, circuit-level proxy		
3—Network—IP	Packet filtering, address filtering, packet filtering firewall	Router or layer three firewall	
2—Data link		Bridging or transparent firewalls	
1—Physical			

Figure 2: Basic firewall functionality and technology versus the OSI model

Figure 3: Positive filtering

Figure 4: Negative filtering

fashion. Initially, the first rule in a firewall is generally to block all traffic, followed by exception rules allowing through the packets specified in the filter table (positive filtering). Conversely, the first rule could be to allow all traffic to pass through the firewall, followed by exception rules in a filter table specifying which traffic must be blocked (negative filtering). Filters can be applied as easily to traffic going from internal (secure) networks to the Internet (nonsecure) as they can be from the Internet into the secure internal networks. Which packets are allowed and disallowed in either direction can vary based on the order in which the firewall rules are processed. As a result, firewall rule logic can be extremely complicated and must be tested carefully.

Figure 3 illustrates positive filtering, in which only packets meeting the criteria of the firewall's filter tables are allowed through the firewall. Figure 4 illustrates negative filtering, whereby any packet meeting the criteria

of the firewall's filter table is blocked and prevented from passing through the firewall.

A given firewall may, but does not necessarily, offer any or all of the functions discussed below.

Bad-Packet Filtering

The first type of filtering normally done is to remove bad packets, sometimes also referred to as misshapen packets. Such abnormal packets are often used to look for vulnerabilities or to launch attacks such as denial-of-service attacks or distributed-denial-of-service attacks. Bad packet filtering can be, and often is, implemented in an edge router, sometimes referred to as a filtering router, that faces the dirty network. However, it is highlighted here as an initial firewall function to ensure that it is not overlooked. More specific examples of bad packets are packet fragments, packets with abnormally set flags, time to live

(TTL) fields, abnormal packet length, or Internet control message protocol (ICMP) packets. The overall purpose in removing such “trash” initially is that the processing-intensive firewall can spend its time looking only at legitimate (although not necessarily authorized) packets. In this manner, bad packets are removed by the edge routers before reaching the firewall, thereby freeing the firewall from ever having to deal with these bad packets.

Address Filtering

This function can, and perhaps should, be performed by a device other than the firewall, such as a border router. Based on address filter tables containing allowed or disallowed individual or groups (subnets) or addresses, address filtering blocks all traffic that contains either disallowed source or destination addresses. Address filtering by itself may not provide adequate protection because it has too large a granularity for some protective requirements, but it does provide a first line of defense against attack techniques such as address spoofing.

Port Filtering

Port filtering goes beyond address filtering, examining to which function or program a given packet applies. For example, file transfer protocol (FTP) typically uses ports 20 and 21, inbound electronic mail (simple mail transfer protocol, or SMTP) typically uses port 25, and inbound nonencrypted Web traffic (hypertext transfer protocol, or HTTP) typically uses port 80. Attacks are often targeted and designed for specific ports. Port filtering can be used to ensure that all ports are disabled except those that must remain open and active to support programs and protocols required by the owners of the inside network. Static port filtering leaves authorized ports open to all traffic all the time, whereas dynamic port filtering opens and closes portions of protocols associated with authorized ports over time as required for the specifics of the protocols.

Domain Filtering

Domain filtering applies to outbound traffic headed through the firewall to the Internet. It can block traffic with domains that are not authorized for communications or can be designed to permit exchanges only with authorized “outside” domains.

Network Address Translation

When organizations connect to the Internet, the addresses they send out must be globally unique. In most cases, an organization’s Internet service provider specifies these globally unique addresses. Most organizations have relatively few globally unique public addresses compared with the actual number of network nodes on their entire network.

The Internet Assigned Numbers Authority has set aside the following private address ranges for use by private networks:

10.0.0.0 to 10.255.255.255
172.16.0.0 to 172.31.255.255
192.168.0.0 to 192.168.255.255

Traffic using any of these “private” addresses must remain on the organization’s private network to interoperate properly with the rest of the Internet. Because anyone is welcome to use these address ranges, they are not globally unique and therefore cannot be used reliably over the Internet. Computers on a network using the private IP address space can still send and receive traffic to and from the Internet by using network address translation (NAT). An added benefit of NAT is that the organization’s private network is not as readily visible from the Internet.

All of the workstations on a private network can share a single or small number of globally unique assigned public IP address(es) because the NAT mechanism maintains a table that provides for translation between internal addresses and ports and external addresses and ports. The combination of the shared public IP address and a port number that is translated into internal address and port numbers via the translation table allows computers on the private network to communicate with the Internet through the firewall. NAT can also run on routers, dedicated servers, or other similar devices, and “gateway” computers often provide a similar function.

Dynamic NAT entries are created automatically in the NAT table as the firewall or router receives packets that require NAT translation. Dynamic NAT entries are purged after a preset period. For mapping addresses on a more permanent basis through the firewall, static NAT entries can be manually entered into the NAT table and must be manually removed as well. Most firewalls provide some type of NAT functionality as illustrated in Figure 5.

Data Inspection

The primary role of many firewalls is to inspect the data passing through it using a set of rules that define what is and is not allowed through the firewall and then to act appropriately on packets that meet required criteria. The various types of firewalls, described in the next section, differ primarily in what portions of the overall data packet are inspected, the types of inspections that can be done, and what sorts of actions are taken with respect to that data. Among the data elements that are commonly inspected are the following:

- IP address
- TCP port number
- User datagram protocol port number
- Data field contents

Contents of specific protocol payloads, such as HTTP, can be inspected in order to subsequently filter out certain classes of traffic (e.g., streaming video, voice, music, etc.). Other data-field content that can be checked for and filtered includes access requests to restricted Web sites, information with specific markings (e.g., proprietary information), or content with certain words or page names.

NAT Source/Destination Table

Private Source IP Address	Private Source Assigned Port ID
192.168.1.22	61001
192.168.1.23	61002
192.168.1.24	61003
192.168.1.25	61004
and so on...	and so on...

Figure 5: NAT functionality

GOLDMAN & RAWLES: ADC3e
FIG. 09-13

Virus Scanning and Intrusion Detection

Some firewalls also offer functionality such as virus scanning and intrusion detection. Advantages of such firewalls include the following:

- “One-stop shopping” for a wide range of requirements
- Reduced overhead from centralization of services
- Reduced training and maintenance

Disadvantages include the following:

- Increased processing load requirements
- Single point of failure for security devices
- Increased device complexity
- Potential for reduced performance over customized subsolutions

Other Functions

Some firewalls also offer functions such as the following:

- VPN (virtual private networks): VPN functionality, allowing secure communication over the Internet, was typically provided by separate, dedicated devices. VPN traffic would have to be decrypted from the VPN tunnel and then passed through a separate firewall for filtering. By combining the VPN functionality with the firewall functionality on a single box, the process is somewhat simplified.
- Usage monitoring, traffic monitoring, and traffic logging: These functions provide usage statistics that can be valuable for capacity planning and also provide

information to troubleshoot problems or spot potential abuse.

- Protection against some forms of IP address spoofing
- Protection against denial-of-service attacks
- Quality of service (QoS): QoS management provides differentiated levels of service (bandwidth, delay, routes) for different types of network traffic

FIREWALL TYPES

Another difficulty with firewalls is that there are no standards for firewall types, configuration, or interoperability. As a result, users must often be aware of how firewalls work to use them, and owners must be aware of these issues to evaluate potential firewall technology purchases. Many different devices can all be called firewalls, but that does not imply that these devices provide identical or even similar functionality. Firewall types and configuration are explained in the next few sections.

Bastion Host

Many firewalls, whether software- or hardware-based, include a bastion host—a specially hardened server or a trusted system designed so that the functionality of the device cannot be compromised by attacking vulnerabilities in the underlying operating system software over which its firewall application software runs. Specifically, the bastion host uses a secure version of the operating system with the most recent patches, security updates, and minimum number of applications to avoid known and unknown vulnerabilities. A bastion host is nothing more than the platform on which the firewall software is installed,

Figure 6: Bastion host

configured, and executed. Once configured with firewall software, the bastion host sits between clean and dirty networks providing a perimeter defense, as illustrated in Figure 6.

Bridging or Transparent Firewalls

Typical firewalls are installed between two or more sub-networks in order to filter traffic between those networks. Multiple network interface cards reside in the firewall and have IP addresses that belong to the respective sub-networks connected to the firewall via a given network interface card. These typical, or layer three, firewalls always must have network interface cards that are assigned IP addresses from surrounding networks. This presents a problem when a layer three firewall needs to be added to an existing network. Addressing schemes and routing tables must be adjusted in such a case. This can be a very time consuming and complex task.

Fortunately, there is a simpler way to add a firewall to an existing network. A layer two or transparent or bridging firewall works at layer two of the OSI model. The network interface cards in a transparent firewall do not require IP addresses. As a result, the network interface cards in these firewalls cannot be accessed directly from the outside, hence the term “transparent” firewall. Transparent or bridging firewalls can be created in at least two ways. Operating systems such as Linux and OpenBSD provide support for configuring a bridging firewall. Router-based or layer three firewalls also often can support transparent bridging firewalls in addition to layer three functionality. The key benefits of a bridging or transparent firewall are ease of installation and configuration, and the added security offered by the transparency of such devices.

Packet-Filtering Firewalls or Layer Three Firewalls

Every packet of data on the Internet can be identified by a source address (IP address) normally associated with the computer that issued the message and the destination

address (IP address) normally associated with the computer to which the message is bound. These addresses are included in a portion of the packet called the header.

A packet filter can be used to examine the source and destination address of every packet. Network access devices known as routers are among the commonly used devices capable of filtering data packets. Filter tables are lists of addresses with data packets and embedded messages that are either allowed or prohibited from proceeding through the firewall. Filter tables may also limit the access of certain IP addresses to certain services and sub-services. This is how anonymous FTP users are restricted to only certain information resources. It takes time for a firewall server to examine the addresses of each packet and compare those addresses to filter table entries. This filtering time introduces latency to the overall transmission time and may create a bottleneck to high volumes of traffic. Hardware implementations of such filters are often used to provide low latency and high throughput.

A filtering program that only examines source and destination addresses and determines access based on the entries in a filter table is known as a network-level filter or packet filter. The term *network level* or *network layer* in this case refers to the network layer or layer three of the OSI Model (see Figure 2), where IP addresses reside in the TCP/IP protocol stack.

Packet-filter gateways can be implemented on routers. This means that an existing piece of technology can be used for dual purposes. Maintaining filter tables and access rules on multiple routers is not a simple task, and packet filtering of this sort is limited in what it can accomplish because it examines only certain areas of each packet. Dedicated packet-filtering firewalls are usually easier to configure and require less in-depth knowledge of protocols to be filtered or examined. One easy way that many packet filters can be defeated by attackers is a technique known as IP spoofing. Because these simple packet filters make all filtering decisions based on IP source and destination addresses, an attacker can often create a packet designed to appear to come from an authorized or trusted IP address, which will then pass through such a firewall unimpeded.

Circuit-Level Gateways and Proxies

Circuit-level proxies, or circuit-level gateways, provide proxy services for transport layer (layer four) protocols such as TCP. Socks, an example of such a proxy server, creates proxy data channels to application servers on behalf of the application client. Socks uniquely identifies and keeps track of individual connections between the client and server ends of an application communication over a network. Like other proxy servers, both a client and a server portion of the Socks proxy are required to create the Socks tunnel. Some Web browsers have the client portion of Socks included, whereas the server portion can be added as a further application to a server functioning as a proxy server. The Socks server would be located inside an organization's firewall and can block or allow connection requests, based on the requested Internet destination, TCP port ID, or user identification. Once Socks approves and establishes the connection through the proxy server, it does not care which protocols flow through the established connection. This is in contrast to other more protocol-specific proxies such as Web proxy, which allows only HTTP to be transported, or WinSock Proxy, which allows only Windows application protocols to be transported.

Because all data go through Socks, it can audit, screen, and filter all traffic in between the application client and server. Socks can control traffic by disabling or enabling communication according to TCP port numbers. Socks4 allowed outgoing firewall applications, whereas Socks5 supports both incoming and outgoing firewall applications, as well as authentication.

The key negative characteristic of Socks is that applications must be "socksified" to communicate with the Socks protocol and server. In the case of Socks4, this meant that local applications had to be recompiled using a Socks library that replaced its normal library functions. However, with Socks5, a launcher is used that avoids "socksification" and recompilation of client programs that in most cases do not natively support Socks. Socks5 also uses a private routing table and hides internal network addresses from outside networks.

Application Gateways

Application gateways are concerned with what services or applications a message is requesting in addition to who is making that request. Connections between requesting clients and service providing servers are created only after the application gateway is satisfied as to the legitimacy of the request. Even once the legitimacy of the request has been established, only proxy clients and servers actually communicate with each other. A gateway firewall does not allow actual internal IP addresses or names to be transported to the external nonsecure network, except as this information is contained within content that the proxy does not control. To the external network, the proxy application on the firewall appears to be the actual source or destination, as may be the case.

Application-level filters, sometimes called "assured pipelines," "application gateways," or "proxy servers," go beyond port-level filters in their attempts to control packet flows. Whereas port-level filters determine the legitimacy

of the IP addresses and ports within packets, application-level filters are intended to provide increased assurance of the validity of packet content in context. Application-level filters typically examine the entire request for data rather than just the source and destination addresses. This ability to examine the entire contents of a data packet in the context of its intended application is sometimes referred to as deep packet inspection. Controlled files can be marked as such, and application-level filters can be designed to prevent those files from being transferred, even within packets authorized by port-level filters. Of course, this increased level of scrutiny comes at the cost of a slower or more expensive firewall.

Proxies are also capable of approving or denying connections based on directionality. Users may be allowed to upload but not download files. Some application-level gateways have the ability to encrypt communications over these established connections. The level of difficulty associated with configuring application-level gateways versus router-based packet filters is debatable. Router-based gateways tend to require a more intimate knowledge of protocol behavior, whereas application-level gateways deal predominantly at the application layer of the protocol stack. Proxies tend to introduce increased latency compared with port-level filtering. The key weaknesses of an application-level gateway is their inability to detect embedded malicious code such as Trojan horse programs or macro viruses and the requirement of more complex and resource-intensive operation than lower-level filters.

Certain application-level protocol commands that are typically used for probing or attacking systems can be identified, trapped, and removed. For example, SMTP is an e-mail interoperability protocol that is a member of the TCP/IP family and used widely over the Internet. It is often used to mask attacks or intrusions. Multipurpose Internet mail extension (MIME) is another method that is often used to hide or encapsulate malicious code such as Java applets or ActiveX components. Other application protocols that may require monitoring include but are not limited to World Wide Web protocols such as HTTP, telnet, FTP, gopher, and Real Audio. Each of these application protocols may require its own proxy, and each application-specific proxy must be designed to be intimately familiar with the commands within each application that will need to be trapped and examined. For example an SMTP proxy should be able to filter SMTP packets according to e-mail content, message length, and type of attachments. A given application gateway may not include proxies for all potential application-layer protocols.

Trusted Gateway

A trusted gateway or trusted application gateway seeks to relieve all the reliance on the application gateway for all communication, both inbound and outbound. In a trusted gateway, certain applications are identified as trusted and are able to bypass the application gateway entirely and are able to establish connections directly rather than be executed by proxy. In this way, outside users can access information servers and Web servers without tying up the proxy applications on the application gateway. These servers are typically placed in a demilitarized zone (DMZ)

Figure 7: Stateful firewall

so that any failures in the application servers will grant only limited additional access to other systems.

Stateful Firewalls

Rather than simply examining packets individually without the context of previously transmitted packets from the same source, stateful firewalls, sometimes referred to as stateful multi-layer inspection firewalls, store information about past activities and use this information to test future packets attempting to pass through. Stateful firewalls typically review the same packet information as normal simple packet filtering firewalls such as source address, destination address, protocol, port, and flags; however, they also record this information in a connection state table, also referred to as a dynamic state table, before sending the packet on. This table will have an entry for each valid connection established over a particular reference frame. The multi-layer aspect of their functionality refers to the fact that they filter packets at the network, transport, session (connection), and application layers. Although stateful firewalls filter applications and evaluate application packet contents, they do not provide application-specific proxies. They combine the functionality of network packet filters, circuit-level gateways, and application-level gateways while adding the connection-oriented stateful inspection.

Some stateful firewalls keep sequence number information to validate packets even further, so as to protect against some session-hijacking attacks. As each packet arrives to a stateful firewall, it is checked against the connection table to determine whether it is part of an existing connection. The source address, destination address, source port, and destination port of the new packet must match the table entry. If the communication has already been authorized, there is no need to authorize it again and the packet is passed. If a packet can be confirmed to belong to an established connection, it is much less costly to send it on its way based on the connection table rather than to reexamine the entire firewall rule set. This makes a stateful firewall faster than a simple packet-filtering firewall for certain types of traffic patterns, since the packet-filtering firewall treats each connection as a new connection. In addition, because there is a "history" in the state tables,

flags can be analyzed to ensure the proper sequence as in the TCP connection handshake, and the stateful firewall can drop or return packets that are clearly not a genuine response to a request.

As a result, stateful firewalls are better able to prevent some sorts of session hijacking and man-in-the-middle attacks. Session hijacking is very similar to IP spoofing, described earlier, except that it hijacks the session by sending forged acknowledgment (ack) packets so that the victimized computer still thinks it is talking to the legitimate intended recipient of the session. A man-in-the-middle attack could be seen as two simultaneous session hijackings. In this scenario, the hacker hijacks both sides of the session and keeps both sides active and appearing to talk directly to each other when, in fact, the man-in-the-middle is examining and potentially modifying any packet that flows in either direction of the session. Figure 7 illustrates the basic functionality of a stateful firewall.

Internal Firewalls

Not all threats to a network are perpetrated from the Internet by anonymous attackers, and firewalls are not a stand-alone, technology-based quick fix for network security. In response to the reality that most losses due to computer crime involve someone with inside access, internal firewalls have been applied with increasing frequency. Internal firewalls include filters that work on the data-link, network, and application layers to examine communications that occur only within internal networks. Internal firewalls also act as access control mechanisms, denying access to applications for which a user does not have specific access approval. To ensure the confidentiality and integrity of private information, encryption and authentication may also be supported by firewalls, even during internal communications.

Virtual Firewalls and Network Based Firewall Services

Virtual firewalls, also known as virtual firewall systems, provide a single, centralized point of control over multiple distributed firewalls. As enterprise networks have grown in both scale and complexity, it has become more difficult

to manage increasing numbers of firewalls on an individual basis. As a result, centralized firewall-management systems have been developed. Each individual firewall is able to be configured uniquely with its own policies and rule sets. The area of protection provided by each firewall is referred to as its security domain or risk domain. All of the configuration for the distributed firewalls can be done from a single, centralized location. A third-party service provider, such as an Internet VPN provider, may provide virtual firewall services, otherwise known as network-based firewall services.

SWITCHED FIREWALLS—AIR GAP TECHNOLOGY

Some vendors try to assert the strength of their protection by using widely known terms such as *switched firewalls* and *air gap* to characterize their protective mechanisms. One example of such a technology provides the same separation of the clean and dirty networks as firewalls. A hardware-based network switch is at the heart of this technology. The premise of creating a physical disconnection between the clean or secure network (intranet) and the nonsecure or dirty network (Internet) is accomplished by connecting a server on the Internet connection that will receive all incoming requests. This server will connect to an electronic switch that strips the TCP headers and stores the packet in a memory bank, and then the switch disconnects from the external server and connects with the internal server. Once the connection is made, the internal server recreates the TCP header and transmits the packet to the intended server. Responses are made in the reverse order. The physical separation of the networks and the stripping of the TCP headers remove many of the vulnerabilities in the TCP connection-oriented protocol. Of course this provides little additional protection over other firewalls at the content level because content-level attacks are passed through the so-called air gap and responses are returned.

By using high-speed switches for rule checking and packet forwarding, switched firewalls, also known as switch-accelerated firewalls, are able to filter and forward packets at multigigabit speeds. In some switched firewall architectures, separate dedicated devices, sometimes referred to as switched firewall directors perform firewall control functions such as policy and session management, connection-table management, and packet-handling rules specification, thus freeing the dedicated separate switched firewall to perform only rule checking and packet forwarding. In some cases, application-specific filtering is provided on the air gap technology. Such devices may be referred to as application firewall appliances or air gap application firewalls. Figure 8 illustrates air gap functionality.

A protective device that is highly effective at limiting information flow to one direction—so-called digital diode technology—is applied in situations in which the sole requirement is that no information be permitted to leak from one area to the other while information is permitted to flow in the other direction. An example would be the requirement for weather information to be available to

military planning computers without the military plans being leaked to the weather stations. This sort of protection typically uses a physical technology such as a fiber-optic device with only a transmitter on one end and a receiver on the other end to provide high assurance of traffic directionality.

SMALL OFFICE, HOME OFFICE FIREWALLS

As telecommuting has boomed and independent consultants have set up shop in home offices, the need for firewalls for the small office, home office (SOHO) market has grown as well. These devices are often integrated with integrated services digital network-based multiprotocol routers that supply bandwidth on demand capabilities for Internet access. Some of these SOHO firewalls offer sophisticated features such as support for VPNs at a reasonable price. The most expensive of these costs less than \$3,000 and some simpler filtering firewalls cost as little as \$100. Some of these devices combine additional functionality such as NAT, built in hub and switch ports, and load balancing in a combined hardware-software device known as a security appliance. Often DSLs (digital subscriber lines) or cable modems include firewall functionality because of their “always on” connection status.

Software-only solutions are also available. These products are installed on every computer and provide firewall-like functionality to each workstation, thereby effectively eliminating client-side vulnerabilities that may bypass server-based or perimeter firewalls. Additional benefits are that each workstation has an extremely inexpensive solution and that protection can be customized at the system level. A potential problem is that some software-only solutions require all users to be firewall administrators for their computers, losing the economy of scale that was one of the original benefits associated with firewalls, while in other cases, distributed desktop firewall configuration is handled from a centralized control point.

FIREWALL FUNCTIONALITY AND TECHNOLOGY ANALYSIS

Commercially available firewalls usually use either packet filtering or proxies as firewall architecture and add an easy-to-use graphical user interface (GUI) to ease the configuration and implementation tasks. Some firewalls even use industry standard Web browsers as their GUIs. Several certifying bodies and internationally accepted criteria are available to certify various aspects of firewall technology. Common Criteria Evaluation Assurance Level (EAL) 4 has been certified on some firewalls. These evaluation criteria are officially known as “Common Criteria for Information Technology Security Evaluation” ISO/IEC 15408 (National Security Agency and National Institute of Standards and Technology 2006). In addition, ICSA (International Computer Security Association) Labs, a division of TruSecure Corporation offers certification of a variety of security technology including firewalls.

Figure 8: Air gap functionality

In general, certification seeks to ensure the following:

- That firewalls meet the minimum requirements for reliable protection
- That firewalls perform as advertised
- That Internet applications perform as expected through the firewall

Table 1 summarizes some of the key functional characteristics of firewall technology.

ENTERPRISE FIREWALL ARCHITECTURES

Conceptual Design Options of Firewall Architectures

Firewalls, or any security technologies for that matter, are virtually useless without associated security policies and the requisite education and communication that are associated with those policies. Before considering alternative enterprise firewall architectures, the information security

analyst must be sure that the policies to be implemented on that enterprise firewall architecture are clearly understood and rigorously enforced.

Before the correct physical firewall architecture for a given situation can be determined, alternative conceptual design options for firewall architectures must be analyzed. At a high level, there are really two alternative conceptual philosophies to firewall architecture design: (1) defense in depth security, and (2) perimeter security.

Defense in Depth

A defense in depth design philosophy proposes multiple levels of security devices such as firewalls and intrusion-detection devices. The greater the value of the information assets within a given risk domain, the greater the number of layers of security technology must be penetrated in order to reach those information assets. Such a philosophy would seem to assume that intrusion or attack is as likely to come from someone inside a corporate network as from outside that network. Defense in depth at

Table 1: Sample Functional Characteristics of Firewall Technology

FIREWALL FUNCTIONAL CHARACTERISTIC	EXPLANATION/IMPORTANCE
Encryption	Allows secure communication through firewall Encryption schemes supported: DES, 3-DES, AES Encryption key length supported: 40, 56, 128, 168, and 256 bits.
Virtual private network (VPN) support	Allows secure communication over the Internet in a VPN topology VPN security protocols supported: IPSEC, SSL
Application proxies supported	How many application proxies are supported? Internet application protocols (HTTP, SMTP, FTP, telnet, NNTP, WAIS, SNMP, rlogin, ping traceroute)? Real Audio? How many controls or commands are supported for each application?
Proxy isolation	In some cases, proxies are executed in their own protected domains to prevent penetration of other proxies or the firewall operating system should a given proxy be breached.
Operating systems supported	UNIX and varieties; Windows NT, 2000, XP,
Virus scanning included	Because many viruses enter through Internet connections, the firewall is a logical place to scan for viruses.
Web tracking	To ensure compliance with corporate policy regarding use of the World Wide Web, some firewalls provide Web-tracking software. The placement of the software in the firewall makes sense because all Web access must pass through the firewall. Access to certain uniform resource locators (URLs) can be filtered.
Violation notification	How does the firewall react when access violations are detected? Options include SNMP traps, e-mail, pop-up windows, pagers, reports.
Authentication supported	As a major network access point, the firewall must support popular authentication protocols and technology.
Network interfaces supported	Which network interfaces and associated data-link-layer protocols are supported?
System monitoring	Are graphical systems monitoring utilities available to display statistics such as disk usage or network activity by interface?
Auditing and logging	Is auditing and logging supporting? How many types of events can be logged? Are user-defined events supported? Can logged events be sent to SNMP managers?
Attack protection	Following is a sample of the types of attacks that a firewall should be able to guard against: TCP denial-of-service attack, TCP sequence number prediction, source routing and RIP attacks, EGP infiltration and ICMP attacks, authentication server attacks, finger access, PCMAIL access, DNS access, FTP authentication attacks, anonymous FTP access, SNMP access, remote access, remote booting from outside networks; IP, MAC and ARP spoofing and broadcast storms; trivial FTP and filter to and from the firewall, reserved port attacks, TCP wrappers, gopher spoofing, and MIME spoofing.
Attack retaliation/counterattack	Some firewalls can launch specific counterattacks or investigative actions if the firewall detects specific types of intrusions.
Administration interface	Is the administration interface graphical in nature? Is it forms based?

ARP = address resolution protocol; DNS = domain name server; EGP = exterior gateway protocol; DES = data encryption standard; FTP = file transfer protocol; HTTP = hypertext transfer protocol; ICMP = Internet control message protocol; IP = Internet protocol; MAC = media access control; MIME = multipurpose internet mail extension; NNTP = network news transfer protocol; RIP = routing information protocol; SMTP = simple mail transfer protocol; SNMP = simple network management protocol; TCP = transmission control protocol. WAIS = wide area information services.

its extreme would propose server-specific firewalls protecting individual servers. In a physical or building security metaphor, defense in depth would propose biometric locks on every door throughout a building, not just on the outside doors.

Perimeter Security

A perimeter security design philosophy draws an imaginary line, or moat, around the perimeter of the risk domain it is seeking to protect. An underlying design assumption in perimeter security is that threats to the information assets

within the protected risk domain are likely to come only from outside that risk domain. Individual servers within a risk domain are typically not specifically or individually protected. All of the emphasis is on building impenetrable perimeter security architecture. In a physical or building security metaphor, perimeter security would have biometric access to the outside doors or armed guards protecting the entrance to the building, but no further security within the building.

Firewall Architecture Design Elements

Once an overall security or firewall philosophy has been determined, key decisions remain to be made regarding the number and location of these firewalls in relation to the Internet and a corporation's public and private information resources. Each of the alternative enterprise firewall architectures explored in this section attempt to segregate three distinct networks or risk domains:

1. The Internet or other "dirty" networks: contain legitimate customers and business partners as well as hackers
2. The DMZ(s), otherwise known as the screened subnet, neutral zone, or external private network: contains Web servers and mail servers among other information assets
3. The internal private network, otherwise known as the secure network or intranet: contains most valuable corporate information

The firewall architectures described in the following sections represent generalized designs or approaches to firewall architecture design. They are not necessarily mutually exclusive. Elements of various firewall architectures described below may be combined in order to properly meet the security requirements of a particular risk domain. For example, packet-filtering routers could easily, and correctly, be added to any of the other firewall architectures described. Likewise, server- or host-specific firewalls could easily be added to other firewall architectures as well.

PACKET-FILTERING ROUTERS

Functionality

Packets-filtering routers or border routers are often the first devices that face the Internet or dirty network from an

organization network perspective. These packet-filtering routers first remove all types of traffic that should not even be passed to the firewalls. This process is typically fast and inexpensive because it involves only simple processes that are implemented in relatively low-cost hardware. Examples of removed packets include packet fragments, packets with abnormally set flags, TTL, abnormal packet length, or ICMP packets, all of which could potentially be used for attacks or to exploit known vulnerabilities and packets from or to unauthorized addresses and ports. Figure 9 illustrates a packet-filtering router architecture.

Advantages

- Perimeter routers can easily perform this task.
- Fast processing
- No additional expense or specialized equipment
- Filter tables listing bad packets to remove is relatively static; not a lot of maintenance involved.

Disadvantages

- Should not be mistaken as a replacement for a firewall
- Processor speed and memory on the router must be properly sized to handle required throughput.
- Filter tables must be manually maintained.

PERIMETER FIREWALL ARCHITECTURE

Functionality

The perimeter firewall architecture represents the physical implementation of the perimeter security conceptual design described previously. It was, and in some cases still is, the most commonly implemented firewall architecture. All rules processing and packet filtering is performed on the perimeter firewall. It is very important that firewall rules are carefully configured and tested, since there is no additional security provided once past the perimeter firewall. A perimeter firewall architecture implies that all information assets within a risk domain protected in this manner are of equal value and face equal risk. Figure 10 illustrates a perimeter firewall architecture.

Advantages

- Relatively simple to configure and manage

Figure 9: Packet-filtering router architecture

Figure 10: Perimeter firewall architecture

Disadvantages

- Single point of security implies a single point of failure.
- All information assets within risk domain are at risk if perimeter security is breached.

SERVER/HOST FIREWALL ARCHITECTURE

Functionality

The server/host firewall architecture is also known as a screened host architecture. This architecture can be used in combination with other architectures such as the perimeter, DMZ, and multitiered DMZ. A server/host firewall is often software-based and resides/executes on the application server that it is protecting. It is sort of a personal bodyguard for the application server within an otherwise secure environment.

TCPWrapper is just one example of a UNIX-based program that could be considered a limited-function server/host firewall software program. It is a utility that can intercept and log any requests for TCP services. It could be considered a “shim” program, much like a proxy server that sits between the computer connection requesting the service and the actual service itself on the server computer. Server/host firewall software programs such as TCPWrapper may provide some or all of the following functionality:

- Attempts to detect IP address spoofing by performing what is known as a double-reverse lookup of the IP address to ensure that the IP address and hostname match the domain name service (DNS) entry. DNS is a service that translates between commonly remembered names such as *www.wiley.com* and an IP address such as 128.210.114.39.
- Performs address and service filtering to be sure that the requested connection is allowed or authorized
- Logs the connection
- Completes the connection to the requested service

Server/host firewalls such as TCPWrapper often run directly on application servers. Microsoft’s ISA (Internet

Security & Acceleration) server, formerly known as Microsoft Proxy Server, is another example of a software-based firewall package that can run on an application server. This makes them distinct from other software-based firewalls that require a dedicated server. Figure 11 illustrates a server/host firewall architecture.

Advantages

- Relatively easy to install and configure
- Adds server-specific incremental protection to other firewall architectures

Disadvantages

- Ongoing maintenance/management can become difficult as the numbers of individual server/host firewalls are installed unless some type of centralized firewall management system is used.

SCREENED SUBNET (DMZ) FIREWALL ARCHITECTURE

Functionality

Rather than using only the packet-filtering router as the front door to the DMZ, a second firewall is added behind the packet-filtering router to further inspect all traffic bound to or from the DMZ. The initial application gateway or firewall still protects the perimeter between the DMZ and the intranet or secure internal network.

A DMZ is considered a neutral or safe zone. Outbound communications from the clean network to the Internet can go through proxy servers in the DMZ. The general public accessing this network from the Internet would be able to access only servers located in the DMZ. The DMZ contains mail, Web, and often e-commerce servers. Servers located behind the DMZ firewall on the clean network behind the DMZ would not be accessible by the general public from the Internet. Figure 12 illustrates a screened subnet (DMZ) firewall architecture. Although this logical diagram would suggest that multiple distinct firewalls are required to establish a DMZ, this is actually not the case. Numerous vendors sell “multilegged” (multiple interface)

Figure 11: Server/host firewall architecture

Figure 12: Screened subnet (DMZ) firewall architecture

firewalls that allow both DMZ or Internet-accessible networks as well as clean or protected networks to be physically attached to a single firewall device.

Advantages

- Provides flexibility especially for Internet-based applications such as e-mail, Web services, and e-commerce
- Allows servers that must be accessible to the Internet while still protecting back-office services on the secure internal network or Intranet

Disadvantages

- More complicated rule configuration means more likelihood of errors.
- Applications running in DMZ may still need access to servers/resources in the secure internal network.
- Once through the server between the DMZ and the Internal network, there is no further protection or differentiated levels of security.

MULTITIERED/DISTRIBUTED DMZ ARCHITECTURE

Functionality

As e-commerce and e-business have proliferated, the need for e-commerce servers to access more and more secure information from database and transaction servers within the secure intranet has increased proportionately. As a result, the number of connections allowed through firewalls into the most secure areas of corporate networks has increased dramatically. In response to this phenomenon, the model of a multitiered DMZ has developed. Such a scenario really builds on the screened subnet firewall (DMZ) architecture by adding additional tiers to the DMZ, each protected from other tiers by additional firewalls. Typically, the first tier of the DMZ closest to the Internet would contain only the presentation or Web portion of the e-commerce application running on Web servers.

A firewall would separate that first tier of the DMZ from the second tier that would house the business logic and application portions of the e-commerce application

Figure 13: Multitiered/distributed DMZ architecture (DB 5 database)

typically running on transaction servers. This firewall would have rules defined to allow only packets from certain applications on certain servers with certain types of requests through from the first-tier DMZ to the second-tier DMZ. The third (most secure) tier of the DMZ is similarly protected from the second tier by a separate firewall. The servers in the third-tier DMZ would be database servers and should contain only the data necessary to complete requested e-commerce transactions. Finally, as in the screened subnet firewall architecture, a firewall would separate the third-tier DMZ from the intranet, or most secure corporate network. Figure 13 illustrates the multitiered/distributed firewall architecture.

Advantages

- When combined with screened host/server specific firewalls, a multitiered DMZ firewall architecture provides good protection for back-office systems such as payroll and inventory servers.
- A multitiered DMZ system provides the greatest level of flexibility and highest number of risk domains, thus providing the ability for optimal placement of information resources

Disadvantages

- Each additional level of firewalls adds a level of complexity in terms of rule configuration and opportunity for configuration errors that can lead to security breaches.
- There is obviously a proportional increase in expense for each level of security/DMZ added.

AIR GAP ARCHITECTURE

Functionality

A hardware-based network switch is at the heart of the air gap architecture. The premise of creating a physical

disconnection between the clean or secure network (intranet) and the nonsecure or dirty network (Internet) is accomplished by placing a server on the Internet connection that will receive all incoming requests. This server will connect to an electronic switch that strips the TCP headers and stores the packet in a memory bank, and then the switch disconnects from the external server and connects with the internal server. Once the connection is made, the internal server recreates the TCP header and transmits the packet to the intended server. Responses are made in the reverse order. The physical separation of the networks and the stripping of the TCP headers remove many of the vulnerabilities in the TCP connection-oriented protocol. Of course this provides little additional protection over other firewalls at the content level because content-level attacks are passed through the so-called air gap and responses are returned.

By using high-speed switches for the rule checking and packet forwarding, switched firewalls, also known as switch-accelerated firewalls are able to filter and forward packets at multigigabit speeds. In some switched firewall architectures, separate dedicated devices, sometimes referred to as switched firewall directors, perform firewall control functions such as policy and session management, connection-table management, and packet-handling rules specification, thus freeing the dedicated separate switched firewall to perform only rule checking and packet forwarding. In some cases, application-specific filtering is provided on the air gap technology. Such devices may be referred to as application firewall appliances or air gap application firewalls. Figure 14 illustrates an air gap architecture.

Advantages

- Provides switched connections between clean and dirty network thereby creating a physical gap or moat between the two.

Figure 14: Air gap architecture

- High-speed network switches at the heart of the air gap architecture provide high throughput.

Disadvantages

- Effectiveness of the architecture is still dependent on the effectiveness of the packet filtering rules within the air gap device.
- Deep packet inspection or content/application-specific inspection cannot be assumed.
- Vendors loosely interpret the term *air gap technology*. Specific functionality of any given device should not be assumed.

CONCLUSION

Firewalls are an essential and basic element of many organizations' security architecture. Nonetheless, technology must be chosen carefully to ensure that it offers the required functionality, and firewalls must be arranged into properly designed enterprise firewall architectures and properly configured, maintained, and monitored. Even in the best circumstances, firewalls should be seen as a relatively small solution within the overall information-protection challenge and should not be considered sufficient on their own.

There is no single firewall architecture that is the correct choice for all security scenarios. Firewall architectures vary primarily in the number of firewalls used and

the placement of those firewalls relative to each other, the information resources they are trying to protect, and the dirty networks or threats they are trying to protect the information resources from. A thorough security-requirements analysis is prerequisite to firewall architecture choice. Such an analysis must start with a detailed understanding of the applications that must be secured. Firewalls, and their arrangement in a particular architecture, are just one piece of the overall security framework puzzle.

GLOSSARY

Address Filtering: A firewall's ability to block or allow packets based on Internet protocol addresses.

Air Gap Technology: Switched connections established to connect external and internal networks that are not otherwise physically connected.

Application-Level Gateway: Application-level filters examine the entire request for data rather than only the source and destination addresses.

Bastion Host: Hardened server with trusted operating system that serves as the basis of the firewall.

Circuit-Level Proxies: Proxy servers that work at the circuit level by proxying protocols such as file transfer protocol.

Demilitarized Zone (DMZ): A neutral zone between firewalls or between a packet filtering router and a firewall in which mail and Web servers are often located.

Domain Filtering: A firewall's ability to block outbound access to restricted sites.

Dual-Homed Host: A host firewall with two or more network interface cards with direct access to two or more networks.

Ephemeral Ports: Port numbers that are temporarily assigned to client-side connections from a predetermined range of available port numbers.

Firewall: A network device capable of filtering unwanted traffic from a connection between networks.

Internal Firewalls: Firewalls that include filters that work on the data-link, network, and application layers to examine communications that occur only on an organization's internal network, inside the reach of traditional firewalls.

Multitiered DMZ: A DMZ that segments access areas with multiple layers of firewalls.

Network Address Translation: A firewall's ability to translate between private and public globally unique Internet protocol addresses.

Packet-Filtering Gateway: A firewall that allows or blocks packet transmission based on source and destination Internet protocol addresses.

Port Filtering: A firewall's ability to block or allow packets based on transmission control protocol port number.

Proxy Server: Servers that break direct connections between clients and servers and offer application- and circuit-layer-specific proxy services to inspect and control such communications.

Screened Subnet: Enterprise firewall architecture that creates a DMZ.

Stateful Firewall: A firewall that monitors connections and records packet information in state tables to make forwarding decisions in the context of previous transmitted packets over a given connection.

Trusted Gateway: In a trusted gateway, certain applications are identified as trusted, are able to bypass the application gateway entirely, and are able to establish connections directly rather than by proxy.

INTRODUCTION

An authentication process establishes the identity of some entity under scrutiny. For example, a traveler authenticates herself to a border guard by presenting a passport. Possession of the passport and resemblance to the attached photograph are deemed sufficient proof that the traveler is the identified person. The act of validating the passport (by checking a database of known passport serial numbers) and assessing the resemblance of the traveler to the photograph is a form of authentication.

On the Internet, authentication is somewhat more complex; network entities do not typically have physical access to the parties they are authenticating. Malicious users or programs may attempt to obtain sensitive information, disrupt service, or forge data by impersonating valid entities. Distinguishing these malicious parties from valid entities is the role of authentication, and is essential to security.

Successful authentication does not imply that the authenticated entity is given access. An authorization process uses authentication, possibly with other information, to make decisions about whom to give access. For example, not all authenticated travelers will be permitted to enter the country. Other factors, such as the existence of visas, past criminal record, and political climate will determine which travelers are allowed to enter the country.

Although the proceeding has focused on entity authentication, it is important to note that other forms of authentication exist. In particular, message authentication is the process by which a particular message is associated with some sending entity. Message authentication is a continuous process, in which the sender of each new message must be constantly evaluated. Such evaluation is typically performed with respect to some identity previously authenticated—that is, through entity authentication. This chapter restricts itself to entity authentication, deferring discussion of forms to other entries in this book.

Introducing Alice and Bob

Authentication is often illustrated through the introduction of two protagonists, Alice and Bob. In these descriptions, Alice attempts to authenticate herself to Bob. Note that in practice, Alice and Bob may not be users, but computers. For example, a computer must authenticate itself to a file server prior to being given access to its contents. Independent of whether Alice is a computer or person, she must present evidence of her identity. Bob evaluates this evidence, commonly referred to as a credential. Alice is deemed authentic (is authenticated) by Bob if the evidence is consistent with information associated with her claimed identity. The form of Alice's credential determines the strength and semantics of authentication.

The most widely used authentication credential is a password. To illustrate, UNIX passwords configured by system administrators reside in the `/etc/passwd` file. During the log-in process, Alice (a UNIX user) types her password into the host console. Bob (the authenticating UNIX operating system) compares the input to the known password. Bob assumes that Alice is the only entity in possession of the password. Hence, Bob deems Alice authentic because she is the only one who could present the password credential.

Note that Bob's assertion that Alice is the only entity who could have supplied the password is not strictly accurate. Passwords are subject to *guessing* attacks. Such an attack continually retries different passwords until the authentication is successful. Many systems combat this problem by disabling authentication of that identity after a threshold of failed authentication attempts. The more serious *dictionary* attack makes use of the UNIX password file itself. Passwords are not stored in their original form. The password and a random salt value are cryptographically hashed when the result is stored. Because the hash function is guaranteed to be noninvertible, someone who gains access to the password file cannot trivially recover the passwords. However, a malicious party who

obtains the password file can mount a dictionary attack by comparing hashed, salted password guesses against the password file's contents. Such an attack debilitates the authentication service, and hence is difficult to combat. Recent systems have sought to mitigate attacks on the password file by placing the password hash values in a highly restricted *shadow password* file.

Passwords are subject to more fundamental attacks. In one such attack, the adversary simply obtains the password from Alice directly. This can occur where Alice "shares" her password with others, or when she records it in some obvious place (e.g., on her PDA). Such attacks illustrate an axiom of security: a system is only as secure as the protection afforded to its secrets. In the case of authentication, failure to adequately protect credentials from misuse can result in compromise of the system.

Particularly in cases in which the substance of the interaction has monetary value, it is important for Alice and Bob to perform *mutual authentication*: not only must Alice prove her identity to Bob, but Bob must also prove his identity to Alice. If this bidirectional authentication is not performed, any adversary can exploit Alice by pretending to be Bob. In fact, attacks on the lack of effective mutual authentication lie at the heart of one of the most dangerous and costly attacks on the Internet today, phishing. In a phishing attack, the adversary uses some medium, such as e-mail, to pose as some important entity, and then uses fake Web sites and other means to coerce the victim into exposing authenticating information such as passwords. Attacks in which the adversary interposes himself between the victim and the real authority fall into the class of *man-in-the-middle* attacks.

The definition of *identity* has historically been controversial. This is largely because authentication does not truly identify physical entities, but associates some secret or (presumably) unforgeable information with a virtual identity. Hence, for the purposes of authentication, any entity in possession of Alice's password is Alice. The strength of authentication is determined by the difficulty with which a malicious party can circumvent the authentication process and incorrectly assume an identity. In our above example, the strength of the authentication process is largely determined by the difficulty of guessing Alice's password. Note that other factors, such as whether Alice chooses a poor password or writes it on the front of the monitor, will determine the effectiveness of authentication. The lesson here is that authentication is as strong as the weakest link; failure to protect the password by either Alice or the host limits the effectiveness of the solution.

Authentication on the Internet is often more complex than suggested by the previous example. Often, Alice and Bob are not physically colocated. Hence, both parties will wish to authenticate each other. In our above example, Alice will wish to ensure that she is communicating with Bob. However, no formal process is needed; because Alice is sitting at the terminal, she assumes that Bob (the host) is authentic.

On the Internet, it is not always reasonable to assume that Alice and Bob have established (or can establish) some relationship prior to communication. For example, consider the case in which Alice is purchasing goods on the Internet. Alice goes to Bob's Web server, identifies the

goods she wishes to purchase, provides her credit card information, and submits the transaction. Alice, being a cautious customer, wants to ensure that this information is being given only to Bob's Web server (i.e., she wants to authenticate the Web server). In general, however, requiring Alice to establish a direct relationship with each vendor from whom she may purchase goods is not feasible (e.g., it is not feasible to establish passwords for each Web site out of band).

Enter Trent, the trusted third party. Logically, Alice appeals to Trent for authentication information relating to Bob. Trent is trusted by Alice to assert Bob's authenticity. Therefore, Bob need only establish a relationship with Trent to begin communicating with Alice—that is, Trent vouches for the identity of Bob. Because the number of widely used trusted third parties is small (on the order of tens), and every Web site establishes a relationship with at least one of them, Alice can authenticate virtually every vendor on the Internet.

CREDENTIALS

Authentication is performed by the evaluation of credentials supplied by the user (i.e., Alice). Such credentials can take the form of something you know (e.g., password), something you have (e.g., smart card), or something you are (e.g., fingerprint). The credential type is specific to the authentication service, and reflects some direct or indirect relationship between the user and the authentication service.

Credentials often take the form of shared secret knowledge. Users authenticate themselves by proving knowledge of the secret. In the UNIX example above, knowledge of the password is deemed sufficient evidence to prove user identity. In general, such secrets need not be statically defined passwords. For example, users in one-time password authentication systems do not present knowledge of secret text, but identify a numeric value valid only for a single authentication. Users need not present the secret directly, but demonstrate knowledge of it (e.g., by presenting evidence that could only be derived from it).

Secrets are often long random numbers, and thus cannot be easily remembered by users. For example, a typical RSA private key is a 1024-digit binary number. Requiring a user to remember this number is, at the very least, unreasonable. Such information is frequently stored in a file on a user's host computer, a PDA, or other nonvolatile storage. The private key is used during authentication by accessing the appropriate file. However, private keys can be considered "secret knowledge" because the user presents evidence external to the authentication system (e.g., from the file system).

Credentials may also be physical objects. For example, a smart card may be required to gain access to a host. Authenticity in these systems is inferred from possession, rather than from knowledge. Note that there is often a subtle difference between the knowledge- and possession-based credentials. For example, it is often the case that a user-specific private key is stored on an authenticating smart card. In this case, however, the user has no ability to view or modify the private key. The user can be authenticated only via the smart card issued to the user. Hence, for

the purposes of authentication, the smart card is identity; no amount of effort can modify the identity encoded in the smart card.¹

Biometric devices measure physical characteristics of the human body. An individual is deemed authentic if the measured aspect matches previously recorded data. The accuracy of matching determines the quality of authentication. Contemporary biometric devices include fingerprint, retina, or iris scanners, and face-recognition software. However, biometric devices are primarily useful only when the scanning device is trusted—that is, under control of the authentication service. Although biometric authentication has seen limited use in the Internet, it is increasingly used to support authentication associated with physical security (i.e., governing clean-room access).

Credential use is subject to eavesdropping and replay. For example, any adversary can watch a user type a password from across the room. The adversary later uses the password to gain access to the system. This problem only gets worse in networks: anyone who can get access to the messages used to authenticate users could potentially reuse the data to masquerade as a legitimate user. Such attacks are mitigated in authentication systems by requiring *freshness*. Freshness guarantees that the use of a credential is bounded in time, and hence could not possibly be replayed. The following sections demonstrate several methods for achieving freshness.

Multifactor authentication systems use more than one system to authenticate the user. For example, some systems require both a password and a token to prove identity. These systems can significantly increase the difficulty of attacks on the authentication. It is much harder to both eavesdrop a password and steal a token than it is to do only one or the other. Multifactor systems have been seen as a valuable way to increase security while maintaining the simplicity and ease of use of traditional authentication mechanisms, and have been widely adopted in corporate environments. However, these mechanisms are only as strong as the underlying systems—that is, if the underlying mechanisms are vulnerable, so is the multifactor system.

Credentials need not identify a particular entity, but can be used to prove some characteristic of a community. For example, a concert ticket serves as a credential that the owner has paid or received permission to attend the show. *Reverse turning tests* use tasks that cannot easily be performed by a computer, such as extracting text from complex images. The correct answer shows that a human was involved. Such tests are useful in preventing online “scripted” attacks.

Authentication Services

A number of general-purpose services have been developed to support authentication, credential maintenance, access control, and accounting. For example, RADIUS, DIAMETER, and LDAP-based authentication services have been widely deployed on the Internet. Networks

subscribing to these services defer all authentication-related activities to these centralized services. Each such system can support a range of authentication services and protocols appropriate for the served environment.

In addition to authentication, these services typically implement access control, which regulates access to valued infrastructure or data, for the controlled environment. For example, all users are authenticated when entering most networks. However, this (typically) does not give total access to the entire network. An access control service determines, based on the identity established via authentication, which services that entity user has a right to access (e.g., file servers, printers, etc.). How access control is performed and results presented to the network is beyond the scope of this chapter.

Authentication services exist to simplify network management. Because of the way technology has evolved, the diverse services comprising a network often require different methods of authentication. Supporting the many authentication methods required by an environment (or many instantiations of a single authentication service) can be enormously costly. Administrators can vastly simplify the administrative process by managing a single database of identities in the authentication services. The services can use whatever credentials are deemed necessary, so long as they are supported by the authentication service. Similarly, new applications can be developed and easily integrated with the existing authentication service through well-defined interfaces. Existing authentication services (nearly) universally support the authentication services defined in this chapter.

Biometrics

Biometrics are a class of authentication systems that exploit the unique physical or behavioral characteristics of users. These services measure characteristics such as fingerprints, hand measurements, face recognition, irises, (walking) gait, or others to determine their identity. The measurements are compared for similarity to previously recorded samples using apparatus specialized for the particular biometric system—for example, fingerprint scanners and video cameras. People whose characteristics are “close enough” to the previously recorded measurement are deemed authentic and associated with the appropriate user identity.

Biometrics are often referred to as “something you are” credentials. That is, the credential is an artifact of your person or behavior. This has the advantage that the user does not need to possess or remember the credential, nor can it be lost. Biometrics are limited in the same way: once the characteristic is lost, it cannot be revoked. For example, unlike other credentials such as public keys, a user whose signature is forged cannot change it later. Hence, in practice it is essential to protect the measurements and apparatus from exposure to adversaries.

In practice, the quality of the apparatus used to measure biometric features varies widely. Hence, error is introduced into the process of measurement. For example, mood, lack of sleep, or aging can significantly affect the quality of measurement in a face-recognition system. The similarity of the measurements to the original is

¹In practice, contemporary smart cards can be modified or probed. However, because such manipulation often takes considerable effort and sophistication (e.g., use of an electron microscope), such attacks are beyond the abilities of the vast majority of attackers.

used, rather than an exact match. Biometrics systems compare the measured distance or existence of features between the previously recorded and measured samples. The measured sample is authentic if the distance is small enough or the number of features is large enough based on a system-specific threshold.

The quality of a biometric system is measured in the rate of false positives and false negatives. A false positive occurs when an inauthentic sample is deemed authentic, and a false negative occurs when a authentic sample is deemed inauthentic. These features are in direct proportion to each other and a direct reflection of the threshold value. A high threshold will prevent false positives but incur more false negatives. Conversely, a low threshold will prevent false negatives but incur more false positives. How one selects a threshold (and more broadly a type of biometric system) is dependent on the needs of the environment, the frequency of authentication, and the value of the protected system.

WEB AUTHENTICATION

One of the most prevalent uses of the Internet is Web browsing. Users access the Web via specialized protocols that communicate HTML and XML requests and content. The requesting user's Web browser renders received content. However, it is often necessary to restrict access to Web content. Moreover, the interactions between the user and a Web server are often required to be private. One aspect of securing content is the use of authentication to establish the true or virtual identity of clients and Web servers.

Password-Based Web Access

Web servers initially adopted well-known technologies for user authentication. Foremost among these was the use of passwords. To illustrate the use of passwords on the Web, the following describes the configuration and use of basic authentication in the Apache Web server (Apache 2002). Note that the use of basic authentication in other Web servers is largely similar.

Access to content protected by basic authentication in the Apache Web server is indirectly governed by the password file. Web site administrators create the password file (whose location is defined by the Web site administrator) by entering user and password information using the `htpasswd` utility. It is assumed that the passwords are given to the users using an out-of-band channel (e.g., via e-mail, phone).

In addition to specifying passwords, the Web server must identify the subset of Web content to be password-protected (e.g., set of protected URLs). This is commonly performed by creating an `.htaccess` file in the directory to be protected. The `.htaccess` file defines the authentication type and specifies the location of the relevant password file. For example, located in the content root directory, the following `.htaccess` file restricts access to users who are authenticated via password.

```
AuthName "Restricted Area"
AuthType Basic
AuthUserFile /var/www/webaccess
require valid-user
```

Figure 1: Password authentication on the Web

Users accessing protected content (via a browser) are presented with a password dialog (e.g., similar to the dialog depicted in Figure 1). The user enters the appropriate username and password, and if correct, is given access to the Web content.

Because basic authentication sends passwords over the Internet in cleartext, it is relatively simple to recover them by eavesdropping on the HTTP communication. Hence, basic authentication is sufficient to protect content from casual misuse, but should not be used to protect valuable or sensitive data. However, as is commonly found on commercial Web sites, performing basic authentication over more secure protocols (e.g., secure sockets layer [SSL], see below) can mitigate or eliminate many of the negative properties of basic authentication.

Many password-protected Web sites store user passwords (in encrypted form) in cookies the first time a user is authenticated. In these cases, the browser automatically submits the cookie to the Web site with each request. This approach eliminates the need for the user to be authenticated every time she visits the Web site. However, this convenience has a price. In most single-user operating systems, any entity using the same host will be logged in as the user. Moreover, the cookies can be easily captured and replayed back to the Web site (Fu et al. 2001).

Digest authentication uses challenges to mitigate the limitations of password-based authentication (Franks et al. 1999). Challenges allow authenticating parties to prove knowledge of secrets without exposing (transmitting) them. In digest authentication, Bob sends a random number (nonce) to Alice. Alice responds with a hash of the random number and her password. Bob uses Alice's password (which only he and Alice know) to compute the correct response, and compares it to the one received from Alice. Alice is deemed authentic if the computed and received responses match (because only Alice could have generated the response). Because the hash, rather than the secret, is sent, no adversary can obtain Alice's password from the response.

Single Sign-on

Password authentication is the predominant authentication method on the Web. Users register a username and password with each retailer or service provider with which they do business. Hence, users are often faced

with the difficult and error-prone task of maintaining a long list of usernames and passwords. In practice, users avoid this maintenance headache by using the same passwords on all Web sites. However, this allows adversaries who gain access to the user information on one site to impersonate the user on many others.

A single sign-on (SSO) system defers user authentication to a single, universal authentication service. Users authenticate themselves to the SSO once per session. Subsequently, each service requiring user authentication is redirected to an SSO server that vouches for the user. Hence, the user is required to maintain only a single authentication credential (e.g., SSO password). Note that the services themselves do not possess user credentials (e.g., passwords), but simply trust the SSO to state which users are authentic.

Although SSO services have been used for many years (e.g., see the section on “Kerberos” below), the lack of universal adoption and cost of integration has made their use in Web applications highly undesirable. These difficulties have led to the creation of SSO services targeted specifically to authentication on the Web. One of the most popular of these systems is the Microsoft Passport service (Microsoft 2002). Passport provides a single authentication service and repository of user information. Web sites and users initially negotiate secrets during the Passport registration process (i.e., user passwords and Web site secret keys). In all cases, these secrets are known only to the Passport servers and the registering entity.

Passport authentication proceeds as follows. Users requesting a protected Web page (i.e., page that requires authentication) are redirected to a Passport server. The user is authenticated via a Passport-supplied log-in screen. If successful, the user is redirected back to the original Web site with an authentication cookie specific to that site. The cookie contains user information and site-specific information encrypted with a secret key known only to the site and the Passport server. The Web site decrypts and validates the received cookie contents. If successful, the user is deemed authentic and the session proceeds. Subsequent user authentication (with other sites) proceeds similarly, except that the log-in step is avoided. Successful completion of the initial log-in is noted in a session cookie stored at the user browser and presented to the Passport server with later authentication requests.

Although SSO systems solve many of the problems of authentication on the Web, they are not a panacea. By definition, SSO systems introduce a single point of trust for all users in the system. Hence, ensuring that the SSO is not poorly implemented, poorly administered, or malicious is essential to its safe use. For example, Passport has been shown to have several crucial flaws (Kormann and Rubin 2000). Note that although existing Web-oriented SSO systems may be extended to support mutual authentication, the vast majority have yet to do so.

Certificates

Although passwords are appropriate for restricting access to Web content, they are not appropriate for more general Internet authentication needs. Consider the Web site for an online bookstore *examplebooks.com*. Users wishing to

purchase books from this site must be able to determine that the Web site is authentic. If not authenticated, a malicious party may impersonate *examplebooks.com* and fool the user into exposing his credit card information.

Note that most Web-enabled commercial transactions do not authenticate the user directly. The use of credit card information is deemed sufficient evidence of the user's identity. However, such evidence is typically evaluated through the credit card issuer service (e.g., checking that the credit card is valid and has not exceeded its spending limit) before the purchased goods are provided to the buyer.

The dominant technology used for Internet Web site authentication is public key certificates. Certificates provide a convenient and scalable mechanism for authentication in large distributed environments (such as the Internet). Note that certificates are used to enable authentication of a vast array of other non-Web services. For example, certificates are often used to authenticate electronic mail messages (see the section on “Pretty Good Privacy,” below).

Certificates are used to document an association between an identity and a cryptographic key. Keys in public key cryptography are generated in pairs; a public key and a private key (Diffie and Hellman 1976). As the name would suggest, the public key is distributed freely, and the private key is kept secret. To simplify, any data signed (using a digital signature algorithm) by the private key can be validated using the public key. A valid digital signature can be mapped to exactly one private key. Therefore, any valid signature can be generated only by some entity in possession of the private key. Conversely, keys in secret cryptography use a single shared secret key. Although it is often more efficient than public key algorithms, secret key cryptography requires the communicating parties to negotiate a secret before communicating.

Certificates are issued by certification authorities (CAs). The CA issues a certificate by signing an identity (e.g., domain name of the Web site), validity dates, and a Web site's public key. The certificate is then freely distributed. A user validates a received certificate by checking the CA's digital signature. Note that most browsers are installed with a collection of CA certificates that are invariably trusted (i.e., do not need to be validated). For example, many Web sites publish certificates issued by the VeriSign CA (VeriSign 2002), whose certificate is installed with most browsers. In its most general form, a system used to distribute and validate certificates is called a “public key infrastructure” (PKI).

Certificate technologies such as those supported by pretty good privacy (PGP) are the basis of secure multipurpose Internet mail extension S/MIME standards (Dusse et al. 1998). S/MIME defines protocols, data structures, and certificate management infrastructures for authentication and confidentiality of MIME data. These standards are being widely adopted as a means to secure personal and enterprise e-mail.

Secure Sockets Layer

Introduced by Netscape in 1994, the secure sockets layer (SSL) protocol uses certificates to authenticate Web content. In addition to authenticating users and Web sites,

Figure 2: The SSL protocol: Alice (the client) and Bob (the server) exchange an initial handshake identifying the kind of authentication and configuration of the subsequent session security. As dictated by the authentication requirements identified in the handshake, Alice and Bob may exchange and authenticate certificates. The protocol completes by establishing a session-specific key used to secure (e.g., encrypt) later communication

the SSL protocol negotiates an ephemeral secret key. This key is subsequently used to protect the integrity and confidentiality of all messages (e.g., by encrypting the messages sent between the Web server and the client). SSL continues to evolve. For example, the standardized and widely deployed TLS (transport-layer security) protocol is directly derived from SSL version 3.0.

The use of SSL is signaled to the browser and Web site through the https URL protocol identifier. For example, Alice enters the following URL to access a Web site of interest:

`https://www.example.com`

In response to this request, Alice's browser will initiate an SSL handshake protocol. If the Web site is correctly authenticated via SSL, the browser will retrieve and render Web site content in a manner similar to HTTP. Authentication is achieved in SSL by validating statements signed by private keys associated with the authenticated party's public key certificate.

Figure 2 depicts the operation of the SSL authentication and key agreement process. The SSL handshake protocol authenticates one or both parties, negotiates the cipher-suite policy for subsequent communication (e.g., selecting cryptographic algorithms and parameters), and establishes a master secret. All messages occurring after the initial handshake are protected using cryptographic keys derived from the master secret.

The handshake protocol begins with both Alice (the end-user browser) and Bob (the Web server) identifying a cipher suite policy and session identifying information. In the second phase, Alice and Bob exchange certificates. Note that policy will determine which entities require authentication: as dictated by policy, Alice and/or Bob will request an authenticating certificate. The certificate is validated on reception (e.g., issuance signature checked against CAs whose certificate is installed with the browser). Note that in almost all cases, Bob will be authenticated, but Alice will not. In these cases, Bob typically authenticates Alice using some external means (only when it becomes necessary). For example, online shopping Web sites will not authenticate Alice until she expresses a desire to purchase goods, and her credit card number is used to validate her identity at the point of purchase.

Interleaved with the certificate requests and responses is the server and client key exchange. This process authenticates each side by signing information used to

negotiate a session key. The signature is generated using the private key associated with the certificate of the party to be authenticated. A valid signature is deemed sufficient evidence because only an entity in possession of the private key could have generated it. Hence, signed data can be accepted as proof of authenticity. The session key is derived from the signed data, and the protocol completes with Alice and Bob sending *finished* messages.

HOST AUTHENTICATION

Most computers on the Internet provide some form of remote access, which access allows users or programs to access resources on a given computer from anywhere on the Internet. This access enables a promise of the Internet: independence from physical location. However, remote access has often been the source of many security vulnerabilities. Hence, protecting these computers from unauthorized use is essential. The means by which host authentication is performed in large part determines the degree to which an enterprise or user is protected from malicious parties lurking in the dark corners of the Internet. This section reviews the design and use of the predominant methods providing host authentication.

Remote Log-in

Embodying the small, isolated UNIX networks of old, remote log-in utilities allow administrators to identify the set of hosts and users that are deemed "trusted." Trusted hosts are authenticated by source IP address, hostname, and/or username only. Hence, trusted users and hosts need not provide a username or password.

The rlogin and rsh programs are used to access hosts. Configured by local administrators, the `/etc/hosts.equiv` file enumerates hosts/users that are trusted. Similarly, the `.rhosts` file contained in each user's home directory identifies the set of hosts trusted by an individual user. When a user connects to a remote host with a remote log-in utility, the remote log-in server (running on the accessed host) scans the `hosts.equiv` configuration file for the address and username of the connecting host. If found, the user is deemed authentic and allowed access. If not, the `.rhosts` file of the accessing user (identified in the connection request) is scanned, and access is granted where the source address and username are matched.

The remote access utilities do not provide strong authentication. Malicious parties may trivially forge IP

addresses, domain name service (DNS) records, and user-names (called “spoofing”). Although attempts have been made to address the security limitations of the IP protocol stack (e.g., IPsec, DNSsec), this information is widely accepted as untrustworthy. Remote access tools trade off security for ease of access. In practice, these tools often weaken the security of network environments by providing a vulnerable authentication mechanism. Hence, the use of such tools in any environment connected to the Internet is considered extremely dangerous.

Secure Shell

The early standards for remote access—telnet and ftp—authenticated users by UNIX password. Although the means of authentication were similar to terminal log-in, their use on an open network introduces new vulnerabilities. Primarily, these utilities are vulnerable to password sniffing. Such attacks passively listen on the network for communication between the host and the remote user.² Because passwords are sent in the clear (unencrypted), user-specific authentication information could be recovered. For this reason, the use of these utilities as a primary means of user access has largely been abandoned.³

The secure shell (SSH) (Ylonen 1996) combats the limitations of standard tools by performing cryptographically supported host and/or user authentication. Similar to SSL, a by-product of the authentication is a cryptographic key used to obscure and protect communication between the user and remote host. SSH is not vulnerable to sniffing attacks, and has been widely adopted as a replacement for the standard remote access tools.

SSH uses public key cryptography for authentication. Upon installation, each server host (host allowing remote access via SSH) generates a public key pair. The public key is manually stored at each initiating host (host from which a user will remotely connect). Note that unlike SSL, SSH uses public keys directly, rather than issued certificates. Hence, SSH authentication relies on the due diligence of host administrators to maintain the correct set of host keys.

SSH initiates a session in two phases. In the first phase, the server host is authenticated. The initiating host creates the SSH session by requesting remote access. To simplify, the requesting host generates a random session key, encrypts it with the received host public key of the server, and forwards it back to the server.⁴ The server recovers the session key using its host private key. Subsequent

communication between the hosts is protected using the session key. Because only someone in possession of the host private key could have recovered the session key, the server is deemed authentic.

The second phase of the SSH session initialization authenticates the user. Dictated by the configured policy, the server will use one of the following methods to authenticate the user:

- *.rhosts file*: As described for the remote access utilities above, simply tests whether the accessing user identifier is present in the *.rhosts* file located in the home directory of the user.
- *.rhosts with RSA*: Similar to above, but requires that the accessing host is authenticated via a known and trusted RSA public key.
- *password authentication*: Prompts the user for a local system password. The strength of this approach is determined by the extent to which the user keeps the password private.
- *RSA user authentication*: Authenticates via a user-specific RSA public key. Of course, this requires that the server be configured with the public key generated for each user.

Note that it is not always feasible to obtain the public key of each host that a user will access. Host keys may change frequently (as based on an administrative policy), be compromised, or be accidentally deleted. Hence, when the remote host key is not known (and the configured policy allows it), SSH will simply transmit it during session initialization. The user is asked if the received key should be accepted. If accepted, the key is stored in the local environment and is subsequently used to authenticate the host.

Although the automated key distribution mode does provide additional protection over conventional remote access utilities (e.g., eavesdropping prevention), the authentication mechanism provides few guarantees. A user accepting the public key knows little about its origin (e.g., it may be subject to forgery, man-in-the-middle attacks, etc.). Hence, this mode may be undesirable for some environments.

One-Time Passwords

In a very different approach to combating password sniffing, the S/Key system (Haller 1994) limits the usefulness of recovered passwords. Passwords in the S/Key system are valid only for a single authentication. Hence, a malicious party gains nothing by recovering a previous password (e.g., via eavesdropping of a telnet log-in). Although on the surface the one-time password approach may seem to require that the password be changed following each log-in, the way in which passwords are generated alleviates the need for repeated coordination between the user and remote host.

The S/Key system establishes an ordered list of passwords. Each password is used in order and only once, then discarded. Although the maintenance of the password list may seem like an unreasonable burden to place on a user, the way in which the passwords are generated makes it conceptually simple. Essentially, passwords are

²The physical media over which many local network communication occurs is Ethernet. Because Ethernet is a broadcast technology, all hosts on the local network (subnet) receive every bit of transmitted data. Obviously, this approach simplifies communication eavesdropping. Although eavesdropping may be more difficult over nonbroadcast media (e.g., switched networks), it is by no means impossible.

³ftp is frequently used on the Web to transfer files. When used in this context, ftp generally operates in *anonymous* mode. ftp performs no authentication in this mode, and the users are often restricted to file retrieval only.

⁴In reality, the server initially transmits a short-term public key in addition to the host key. The requesting host encrypts the random value response with both keys. The use of the short-term keys prevents adversaries from recovering the content of past sessions should the host key become compromised.

created such that the knowledge of a past password provides no information on future passwords. However, if one knows a secret value (called a “seed value”), then all passwords are easily computable. Hence, whereas an authentic user can supply passwords as they are needed, a malicious adversary can supply only passwords that have been previously used (and are no longer valid).

In essence, the S/Key system allows the user to prove knowledge of the password without explicitly stating it. Over time, this relatively simple approach has been found to be extremely powerful, and is used as the basis of many authentication services. For example, RSA’s widely used SecurID combines a physical token with one-time password protocols to authenticate users (RSA 2002).

Kerberos

The Kerberos system (Neuman and Ts’o 1994) performs trusted third-party authentication. In Kerberos, users, host, and services defer authentication to a mutually trusted key distribution center (KDC). All users implicitly trust the KDC to act in their best interest. Hence, this approach is appropriate for localized environments (e.g., campus, enterprise), but does not scale well to large, loosely coupled communities. Note that this is not just an artifact of the Kerberos system, but is true of any trusted third-party approach; loosely coupled communities are unlikely to universally trust any single authority.

Depicted in Figure 3, the Kerberos system performs mediated authentication between Alice and Bob through a two-phase exchange with the KDC. When logging onto the system, Alice enters her username and password.

Alice’s host sends the KDC her identity. In response, the KDC sends Alice information that can be understood only by someone in possession of the password—that is, it is encrypted with a key derived from the password. Included in this information is a TGT used later by Alice

to initiate a session with Bob. Alice is deemed authentic because she is able to recover the TGT.

At some later point, Alice wishes to perform mutual authentication with another entity, Bob. Alice informs the KDC of this desire by identifying Bob and presenting the previously obtained TGT. Alice receives a message from the KDC containing the session key and a ticket for Bob. Encrypting the message with a key known only to Alice ensures that its contents remain confidential.

Alice then presents the ticket included in the message to Bob. Note that the ticket returned to Alice is opaque; its contents are encrypted using a key derived from Bob’s password. Therefore, Bob is the only entity that can retrieve the contents of the ticket. Because later communication between Alice and Bob uses the session key (given to Alice and contained in the ticket presented to Bob), Alice is assured that Bob is authentic. Bob is assured that Alice is authentic because Bob’s ticket explicitly contains Alice’s identity.

One might ask why Kerberos uses a two-phase process. Over the course of a session, Alice may frequently need to authenticate a number of entities. In Kerberos, because Alice obtains a TGT at log-in, later authentication can be performed automatically. Thus, the repeated authentication of users and services occurring over time does not require human intervention; Alice types in her password only once.

Note that a KDC authenticates users only within its realm. Users and services in different realms would seem not to be able to authenticate each other. However, protocol extensions allow interrealm authentication by cross registering KDCs. A user contacts its local KDC, which acts as an introducer to the foreign KDC, which in turn enables authentication of the entities as above.

Because of its elegant design and technical maturity, the Kerberos system has been widely accepted in local environments. Historically common in UNIX environments, it has recently been introduced into other operating systems—for example, Windows 2000 and XP.

Figure 3: Kerberos authentication: Alice receives a ticket-granting ticket (TGT) after successfully logging into the Kerberos KDC. Alice performs mutual authentication with Bob by presenting a ticket obtained from the KDC to Bob. Note that Bob need not communicate with the KDC directly; the contents of the ticket serve as proof of Alice’s identity

Pretty Good Privacy

As indicated by the previous discussion of trusted third parties, it is often true that two parties on the Internet will not have a direct means of performing authentication. For example, a programmer in Great Britain may not have any formal relationship with a student in California. Hence, no trusted third party exists to which both can defer authentication. A number of attempts have been made to address this problem by establishing a single public key infrastructure spanning the Internet. However, these structures require users to directly or indirectly trust CAs whose operation they know nothing about. Such assumptions are inherently dangerous, and have been largely rejected by user communities.

The pretty good privacy system (PGP; Zimmermann 1994) takes advantage of social and organizational relationships between users on the Internet. In PGP, each user creates a self-signed PGP certificate identifying a public key and identity information (e.g., e-mail address, phone number, name). Users use the key to sign the keys of users whom they trust. In addition, they obtain signatures from

users who trust them. The PGP signing process is not defined by PGP. Users commonly will exchange signatures with friends and colleagues.

The keys and signatures defined for a set of users defines a web of trust. Upon reception of a key from a previously unknown source, an entity will make a judgment of whether to accept the certificate based on the presence of signatures by known entities. A certificate will likely be accepted if a signature generated by a trusted party (with known and acceptable signing practices) is present. Such assessment can span multiple certificates, in which signatures create trusted linkage between acceptable certificates. However, because trust is not frequently transitive, less trust is associated with long chains. PGP certificates are primarily used for e-mail and software distribution validation, but have been extended to support a wide range of data-exchange systems (e.g., Internet newsgroups).

Internet Protocol Security

Internet protocol security (IPsec; Kent and Atkinson 1998) is emerging as an important service for providing security on the Internet. IPsec is not just an authentication service, but provides a complete set of protocols and tools for securing IP-based communication. The IPsec suite of protocols provides host-to-host security within the operating system implementation of the IP protocol stack. This has the advantage of being transparent to applications running on the hosts. A disadvantage of IPsec is that it does not differentiate between users on the host. Hence, while communication passing between the hosts is secure (as determined by policy), little can be ascertained as to the true identity of users on those hosts.

The central goal of IPsec was the construction of a general-purpose security infrastructure supporting many network environments. Hence, IPsec supports the use of an array of authentication mechanisms. IPsec authentication can be performed manually or automatically. Manually authenticated hosts share secrets distributed via administrators (i.e., configured manually at each host). Identity is inferred from knowledge of the secret. Session keys are directly or indirectly derived from the configured secret.

The Internet security association key management protocol (ISAKMP) defines an architecture for automatic authentication and key management used to support the IPsec suite of protocols. Built on ISAKMP, the Internet key exchange (IKE) protocol implements several protocols for authentication and session key negotiation. In these protocols, IKE negotiates a shared secret and policy between authenticated end points of an IPsec connection. The resulting IPsec security association (SA) records the result of IKE negotiation, and is used to drive later communication between the end points.

The specifics of how authentication information is conveyed to a host are a matter of policy and implementation. However, in all implementations, each host must identify the keys or certificates to be used by IKE authentication. For example, Windows XP provides dialogs used to enter preshared keys. These keys are stored in the Windows registry, and are later used by IKE for authentication and session key negotiation. Note that how the host

stores secrets is of paramount importance. As with any security solution, users should carefully read all documentation and related security bulletins when using such interfaces.

Wireless Networks

Wireless networks are quickly becoming ubiquitous. The ability to get access to the Internet anywhere and at any time is permitting new applications and easing our online and physical lives. However, wireless networks introduce enormous security risks. The omnipresence of wireless permits anyone within range some level of access to sensitive assets. In short, the security perimeter upon which much of traditional network security is based has completely disappeared. This has caused security personnel, developers, and researchers to reevaluate the methods and policies used to govern the digital domain. This is particularly true of authentication.

Wireless networks are defined by the mode in which they operate. There are two predominant modes in use today: ad hoc and infrastructure. In an ad hoc mode, the hosts in the wireless network form a peer-to-peer physical routing infrastructure. That is, each host acts as a router for the other hosts in the network by passing packets between themselves and local access points (devices that route packets between wireless and physical networks). In infrastructure mode, every host must communicate directly with an access point. Because it introduces fewer security and performance concerns and is generally simpler to administer, infrastructure mode is more popular. Independent of the mode, either the access points or peer hosts authenticate new hosts before they are allowed entry into a secure wireless network.

The simplest form of wireless authentication is MAC (media access control) authentication. Each physical network device (e.g., network card) is programmed with a unique MAC address. Because this is guaranteed to be unique, it can be used to identify the devices that should be allowed on the network (e.g., employee laptops). The authenticating device simply looks at the MAC address included in each packet. If it is on the list of approved devices, the packet is allowed. Note that this is not very secure, but it does prevent hosts from inadvertently gaining access to the network. MAC addresses can be trivially spoofed, and moderately sophisticated users easily bypass such authentication measures.

The wired equivalent privacy (WEP) protocol was introduced to solve some of the security issues associated with wireless networks. The WEP protocol aims only to prevent unauthorized parties from gaining access to the network or manipulating packets on the network. WEP assumes that all authorized entities have access to a cryptographic key shared by all authorized parties. In practice, this key is typically generated from a password or pass-phrase entered into some host configuration dialog. WEP specifies how the key is used to encrypt and provide integrity checks for the packet payload. Hence, the WEP key (or password) is used as a credential—access to the password is deemed sufficient proof of identity as an authorized user.

WEP suffers from two central limitations. First, the protocol has a critical design flaw that leaves the WEP

key vulnerable to exposure. This exploit is available in several widely available hacker tools, and has led to the decline of the protocol's use. A second limitation is that the protocol does not identify a particular user or host. Hence, it is difficult to perform accounting and user logging in environments that use WEP as the sole authentication mechanism.

The 802.11i (also known as WPA) standards are designed to address the security limitations of WEP. In addition to addressing transport security (e.g., encryption key management), these standards define a framework for wireless authentication. The authentication framework standard, called 801.1x, provides an architecture in which centralized services authenticate hosts through access points. Existing authentication services can be used for authenticating the hosts (e.g., Kerberos, certificates, etc.), and the standard defines how these methods will be performed in the wireless network.

The centerpiece of the 802.1x standard is the EAP (Extensible Authentication Protocol). EAP is a challenge-response protocol run over secured transport service such as TLS/SSL. Once the secure transport protocol is established, other authentication services such as Kerberos or RADIUS are used to complete authentication. Developed by the CISCO Corporation, LEAP is an instance of the EAP protocol. Wireless clients (e.g., laptops, PC, handhelds) use the LEAP protocol to communicate with RADIUS-enabled gateway devices. Typically, the gateway devices are wireless base stations that connect the wireless network to local wired networks.

Interactive Media

The growth of the Internet has spawned many new ways of communicating. Internet messaging, voice over IP, digital conferencing, collaborative tools, and other media have hastened changes in the way we interact with people all over the globe. However, with these new media comes the need for authentication: we must ensure that we are exposing our data and ourselves only to authenticated users and services.

The H.323 protocol is the dominant tool for interactive media on the Internet. H.323 is a suite of media protocols that control the signaling and data transmission in media calls. The session initialization protocol (SIP) is an evolving framework for IP-based media signaling, and is seen as a replacement for much of H.323. Both H.323 and SIP allow the gatekeeper servers to integrate external authentication services such as RADIUS (remote authentication dial-in user service). Hence, as is the trend on general computing systems, the media applications most frequently defer authentication to specialized services.

CONCLUSION

The preceding sections described but a small fraction of the vast array of available authentication services. Given the huge number of alternatives, one might ask, "which one of these systems is right for my environment?" The following presents several guidelines for the integration of an authentication service with applications and environments.

- *Don't try to build a custom authentication service.* Designing and coding an authentication service is inherently difficult. This fact has been repeatedly demonstrated on the Internet; bugs and design flaws are occasionally found in widely deployed systems, and several custom authentication services have been broken in a matter of hours. It is highly likely that there exists an authentication service that is appropriate for a given environment. For all these reasons, one should use services that have been time-tested.
- *Understand who is trusted by whom.* Any authentication system should accurately reflect the trust held by all parties. For example, a system that authenticates students in a campus environment may take advantage of local authorities. In practice, such authorities are unlikely to be trusted by arbitrary end points in the Internet. Failure to match the trust existing in the physical world has ultimately led to the failure of many services.
- *Evaluate the value of the resources being protected and the strength of the surrounding security infrastructure.* Authentication is useful only when used to protect access to a resource of some value. Hence, the authentication service should accurately reflect the value of the resources being protected. Moreover, the strength of the surrounding security infrastructure should be matched by the authentication service. One wants to avoid "putting a steel door in a straw house." Conversely, a weak or flawed authentication service can be used to circumvent the protection afforded by the surrounding security infrastructure.
- *Understand who or what is being identified.* Identity can mean many things to many people. Any authentication service should model identity as is appropriate for the target domain. For many applications, it is often not necessary to map a user to a physical person or computer, but may treat them as distinct, largely anonymous entities. Such approaches are likely to simplify authentication, and provide opportunities for privacy protection.
- *Establish credentials securely.* Credential establishment is often the weakest point of a security infrastructure. For example, many Web registration services establish passwords through unprotected forms (i.e., via HTTP). Malicious parties can trivially sniff such passwords and impersonate valid users. Hence, these sites are vulnerable even if every other aspect of security is correctly designed and implemented. Moreover, the limitations of many credential establishment mechanisms are often subtle. One should be careful to understand the strengths, weaknesses, and applicability of any solution to the target environment.
- *Authenticate all hosts in wireless environments.* Wireless networks vastly complicate network security. The loss of the traditional security perimeter caused by ubiquitous access mandates that strong protections be put in place to prevent authorized entities from gaining access. Authentication is a necessary component of such protections.

In the end analysis, an authentication service is one aspect of a larger framework for network security. Hence, it

is necessary to consider the many factors that contribute to the design of the security infrastructure. It is only from this larger view that the requirements, models, and design of an authentication system emerge.

GLOSSARY

- Authentication:** The process of establishing the identity of an online entity.
- Authorization:** The process of establishing the set of rights associated with an entity.
- Certificate:** A digitally signed statement associating a set of attributes with a public key. Most frequently used to associate a public key with a virtual or real identity (i.e., identity certificate).
- Credential:** Evidence used to prove identity or access rights.
- Malicious Party:** Entity on the Internet attempting to gain unauthorized access, disrupt service, or eavesdrop on sensitive communication (synonyms: adversary, hacker).
- Secret:** Information known only to and accessible by a specified (and presumably small) set of entities (e.g., passwords, cryptographic keys).
- Trusted Third Party:** An entity mutually trusted (typically by two end points) to assert authenticity or authorization, or perform conflict resolution. Trusted third parties are also often used to aid in secret negotiation (e.g., cryptographic keys).
- Web of Trust:** Self-regulated certification system constructed through the creation of ad hoc relationships between members of a user community. Webs are typically defined through the exchange of user certificates and signatures within the pretty good privacy (PGP) system.

INTRODUCTION

The ancient folk tale of Ali Baba and the Forty Thieves mentions the use of a password. In this story, Ali Baba finds that the phrase “Open Sesame” magically opens the entrance to a cave where the thieves have hidden their treasure. Similarly, modern computer systems use passwords to authenticate users and allow them entrance to system resources and data shares on an automated basis. The use of passwords in computer systems can be traced to the earliest multi-user time-sharing and dial-up networks. There is no evidence that passwords were used before this in purely batch-job systems.

The security provided by a password system depends on the passwords being kept secret at all times. Thus, a password is vulnerable to compromise whenever it is used, stored, or even known. In a password-based authentication mechanism implemented on a computer system, passwords are vulnerable to compromise because of the following exposure areas (Brotman 1985):

1. Passwords are initially assigned to users when they are enrolled on the system. The threat here is that a default password can be guessed and used by an attacker before it is changed by the authorized user. In addition, an attacker could trick a system administrator or user to reset an account password to a default state, allowing an avenue for compromise.
2. Passwords are stored in a “password database” by the system. If an attacker could access the database, he could compromise the security of the passwords stored in it.
3. Users must remember their passwords. Because of the limitations of human memory, users are prone to choose weak or easily guessed passwords, or else they

write down their passwords. Either can lead to compromise by attackers.

4. Users must enter passwords into the system to authenticate. Whenever passwords are entered, an attacker could use a keystroke logger, sniffer, or other device to capture the password and perhaps replay it later.

Because of these factors, a number of protection schemes have been developed for maintaining password security. These include implementing policies and mechanisms to ensure “strong” passwords, encrypting the password database, and simplifying the sign-on and password synchronization processes. Without a “defense-in-depth” approach to securing passwords—that is, implementing all of these methods to provide several layers of security—security administrators will be leaving their systems at risk.

TYPES OF IDENTIFICATION/ AUTHENTICATION

There are three basic ways to verify the identity of users on a system: (1) what they have (e.g., smartcard or hardware token), (2) what they are (e.g., biometric fingerprint [see Figure 1] or iris pattern), and (3) what they know (e.g., personal identification number [PIN] or password).

Of all identity verification methods, passwords are probably weakest because of the exposure factors enumerated above; yet they are still the most widely used method in systems today because password-verification schemes are easily programmed and maintained in automated systems. In order to guarantee strong authentication, a system ought to combine two or more of the verification factors. For example, in order to access an ATM, someone must have a bank card and know her PIN.

Figure 1: A biometric fingerprint reader (photo courtesy of Biometric Access Company)

The manner in which these verification methods are implemented in a system include hardware or software features, operating procedures, management procedures, or a combination of these.

HISTORY OF PASSWORDS IN MODERN COMPUTING

Conjecture as to which system was the first to incorporate passwords was discussed by several computing pioneers on the Cyberspace History List-Server (CYHIST), the archives of which are now maintained by West Virginia University (www.clc.wvu.edu). However, no one ever provided any concrete evidence to support one system or another as being the progenitor. The consensus opinion favors the Compatible Time-Sharing System (CTSS) developed at the Massachusetts Institute of Technology (MIT) Computation Center beginning in 1961. As part of Project

MAC (multiple access computer) under the direction of Professor Fernando J. ("Corby") Corbató, the system was implemented on an IBM 7094 and reportedly began using passwords by 1963.

According to researcher Norman Hardy, who worked on the project, the security of passwords immediately became an issue as well: "I can vouch for some version of CTSS having passwords. It was in the second edition of the CTSS manual, I think, that illustrated the login command. It had Corby's user name and password. It worked—and he changed it the same day" (personal e-mail communication to the author of this chapter).

Passwords were widely in use by the early 1970s as the "hacker" culture began to develop, possibly in tacit opposition to the ARPANET (the precursor to the Internet). By the 1980s, there were published accounts of how passwords had been used to access systems either by guessing or using system default passwords. In the 1990s, sophisticated password-cracking tools began to appear. Incidentally, the technical knowledge required to use such tools did not increase. On the contrary, these tools are simple to use and widely available for free on the Internet (see Figure 2). Now, with the explosion of the World Wide Web, the use of passwords and the quantity of confidential data that those passwords protect have grown exponentially.

However, just as the forty thieves' password protection system was breached (the cave could not differentiate between Ali Baba's voice and those of the thieves), computer password systems have also been plagued by a number of vulnerabilities. The history of password authentication is replete with examples of weak, easily compromised systems. In general, "weak" authentication systems are characterized by protocols that either leak the password directly over the network or leak sufficient information while performing authentication to allow intruders to deduce or guess at the password.

Figure 2: Proliferation of hacking tools

The U.S. Department of Defense Computer Security Center (CSC) recognized this problem and published the *Password Management Guideline* (also known as the “Green Book”) in 1985 “to assist in providing that much needed credibility of user identity by presenting a set of good practices related to the design, implementation and use of password-based user authentication mechanisms.” The Green Book outlined a number of steps that system security administrators should take to ensure password security and suggests that, whenever possible, they be automated. These include the following “Ten Commandments” of passwords:

1. System security administrators should change the passwords for all standard user IDs before allowing the general user population to access the system.
2. A new user should always appear to the system as having an “expired password,” which will require the user to change the password by the usual procedure before receiving authorization to access the system.
3. Each user ID should be assigned to only one person. No two people should ever have the same user ID at the same time, or even at different times. It should be considered a security violation when two or more people know the password for a user ID.
4. Users need to be aware of their responsibility to keep passwords private and to report changes in their user status or suspected security violations. Users should also be required to sign a statement to acknowledge understanding of these responsibilities.
5. Passwords should be changed on a periodic basis to counter the possibility of undetected password compromise.
6. Users should memorize their passwords and not write them on any medium. If passwords must be written,

they should be protected in a manner that is consistent with the damage that could be caused by their compromise.

7. Stored passwords should be protected by access controls provided by the system, by password encryption, or by both.
8. Passwords should be encrypted immediately after entry, and the memory containing the plaintext password should be erased immediately after encryption.
9. Only the encrypted password should be used in comparisons. There is no need to be able to decrypt passwords. Comparisons can be made by encrypting the password entered at log-in and comparing the encrypted form with the encrypted password stored in the password database.
10. The system should not echo passwords that users type in, or at least it should mask the entered password (e.g., with asterisks).

PASSWORD SECURITY—BACKGROUND

Information Theory

According to fundamental work in information theory performed by Claude Shannon (1948), we find that a password is only as good as its entropy, or apparent “randomness.” According to Shannon’s theorems, the quality of a password (i.e., that which keeps an attacker from guessing it) is not necessarily a function of the length of a password or the number of symbols used in it. Rather, it is determined by how many different possible passwords there are and how frequently each is used. The following illustrates this.

Say a user is filling out a form on a Web page (see Figure 3). The form has a space for “Sex,” and leaves six characters for entering either “female” or “male” before

The image shows a screenshot of a Microsoft Internet Explorer window titled "Sample Web Form - Microsoft Internet Explorer". The address bar shows "sample.htm". The main content area displays a form titled "Sample Web Form" with three dots below it. The form contains a text input field with the text "Female" inside, followed by the label "Type in Sex: Male or Female". Below the input field is a "Submit" button. The browser's status bar at the bottom shows "Done" and "My Computer".

Figure 3: Sample Web page entry form

the entry is encrypted and sent to the server. If we consider each character is a byte (8 bits), then $6 \times 8 = 48$ bits will be sent for this response. Is this how much information is actually contained in the field, though? Clearly, there is only 1 *bit* of data represented by the entry—a binary value—either male or female. That means there is only 1 bit of entropy (or uncertainty), and there are 47 bits of redundancy in the field. This redundancy could be used by a cryptanalyst (someone who analyzes crypto-systems) to find regularities between the unencrypted and encrypted text, perhaps allowing him to crack the key and reveal the entire entry.

The same concept applies to password security. A longer password is not necessarily a better password. Rather, a password that is difficult to guess (i.e., one that has high entropy or appears random) is best. This usually comes from a combination of factors (see “Guidelines for Selecting a Strong Password,” below). The probability that any single attempt at guessing a password will be successful is one of the most critical factors in a password system. This probability depends on the size of the password space and the statistical distribution within that space of passwords that are actually used.

However, over the past several decades, Moore’s law (see Glossary) has made it possible to use brute-force methods (i.e., trying all combinations a keyboard can provide) to crack password spaces of larger and larger entropy. This, combined with the fact that there is a limit to the entropy that the average user can remember, means that nowadays passwords are more at risk than ever. A user cannot typically remember a completely random-looking 32-character password—but that is what is required to have the equivalent strength of a 128-bit (i.e., strong) encryption key. Password-cracking tools have advanced to the point of being able to crack nearly anything a system could reasonably expect a user to memorize (see “Password Length and Human Memory,” below).

Cryptographic Protection of Passwords

In early password systems, the most basic and least secure method of authentication was to store passwords in plaintext in a database on a server. During authentication, the client would send his or her password to the server, and the server would compare this against the stored value. Obviously, however, if the password file were accessible to unauthorized users, the security of the system could easily be compromised.

In later systems, developers discovered that a server did not need to store a user’s password in plaintext form in order to perform password authentication. Instead, the password could be transformed through a one-way function, such as a hash function, into a random-looking sequence of bytes. Such a function would be difficult to invert. In other words, given a password, it would be easy to compute its hash, but given a hash, it would be computationally infeasible to derive the password from it (see “Hashing,” below). Authentication would consist merely of performing the hash function over the client’s password and comparing it to the stored value. The password database itself could be made accessible to all users without fear of an intruder being able to steal passwords from it.

According to Cambridge University professor of computing Roger Needham, the Cambridge Multiple Access System (CMAS), which was an integrated online-offline terminal or regular input-driven system, may have been among the earliest to implement such one-way functions. It first went online in 1967, and incorporated password protection. According to Needham: “In 1966, we conceived the use of one-way functions to protect the password file, and this was an implemented feature from day one” (personal e-mail communication to the author of this article).

Hashing

A hash function is an algorithm that takes a variable-length string as input and produces a fixed-length value (the hash) as output. The challenge for a hashing algorithm is to make this process irreversible; that is, finding a string that produces a given hash value should be very difficult. It should also be difficult to find two arbitrary strings that produce the same hash value. This is called a “collision.”

Also called “message digests” or “fingerprints,” several one-way hash functions are in common use today. Among these are Message Digest Algorithm 5 (MD5) and Secure Hash Algorithm 1 (SHA-1). The former was developed by Ron Rivest for RSA Security, Inc., and produces 128-bit hash values. See Table 1 for an example of output generated by MD5. SHA-1 was developed by the U.S. National Institute of Standards and Technology (NIST) and the National Security Agency (NSA), and produces 160-bit hash values. SHA-1 is generally considered more secure than MD5 because of its longer hash value. The longer the output, the harder it is to find a collision.

Microsoft Windows XP uses one-way hash functions to store password information in the security account manager (SAM). There are no Windows32 applications programming interface (API) function calls to retrieve user passwords because the system does not store them. It stores only hash values. However, even a hash-encrypted password in a database is not entirely secure. A cracking tool can compile a list of, say, the one million most commonly used passwords and compute hash functions from all of them. Then the tool can obtain the system account database and compare the hashed passwords in the database with its own list to see what matches. This is called a “dictionary attack” (see “Password-Cracking Tools,” below).

To make dictionary attacks more difficult, some systems use what is called a “salt.” A salt is a random string that is concatenated with a password before it is operated on by the hashing function. The salt value is then stored in the user database, together with the result of the hash function. Using a salt makes dictionary attacks more difficult, as a cracker would have to compute the hashes for all possible salt values.

A simple example of a salt would be to add the time of day; for example, if a user logs in at noon using the password “pass,” the string that would be encrypted might be “1p2a0s0s.” By adding this randomness to the password, the hash will actually be different every time the user logs in (unless he logs in at noon every day). Whether a salt is used and what the salt is depends on the operating system and the encryption algorithm being used. In the FreeBSD

Table 1: Output from the MD5 Test Suite

For the input string	The output message digest is
""(no password)	d41d8cd98f00b204e9800998ecf8427e
"a"	0cc175b9c0f1b6a831c399e269772661
"abc"	900150983cd24fb0d6963f7d28e17f72
"message digest"	f96b697d7cb7938d525a2f31aaf161d0
"abcdefghijklmnopqrstuvwxyz"	c3fcd3d76192e4007dfb496cca67e13b
"ABCDEFGHIJKLMNOPQRSTUVWXYZabc cdefghijklmnopqrstuvwxyz0123456789"	d174ab98d277d9f5a5611c2c9f419d9f
"1234567890123456789012345678901234567 8901234567890123456789012345678901234567890"	57edf4a22be3c955ac49da2e2107b67a

operating system, for example, there is a function called "crypt" that uses the DES (data encryption standard), MD5, or Blowfish algorithms to hash passwords and can also use three forms of salts.

Hashing addresses the secure storage issue, but it does not address another weakness in a networked environment—it is difficult to transmit the password securely to the server for verification without it being captured and reused, perhaps in a replay attack. To avoid revealing passwords directly over an untrusted network, computer scientists have developed "challenge and response" systems. At their simplest, the server sends the user some sort of challenge, which would typically be a random string of characters called a "nonce" (contraction of "number used once") that changes with time. The user then computes a response, usually some function based on both the challenge and the password. This way, even if the intruder captured a valid challenge/response pair, it would not help her gain access to the system, because future challenges would be different and require different responses.

These challenge/response systems are sometimes referred to as one-time password (OTP) systems. Bellcore's S/KEY is one such system in which a one-time password is calculated by combining a seed with a secret password known only to the user and then applying a secure hashing algorithm a number of times equal to the sequence number. Each time the user is authenticated, the sequence number expected by the system is decremented, thus eliminating the possibility of an attacker trying a replay attack using the same password again.

PASSWORD-CRACKING TOOLS

Password-Cracking Approaches

As mentioned above, passwords are typically stored as values hashed with one-way functions. In other words, this entire book could be hashed and represented as 8 bytes of gibberish. There would be no way to use these 8 bytes of data to obtain the original text. However, password crackers know that people do not use whole books as their passwords. The majority of passwords are four to twelve characters in length. Passwords are also, in general,

not just random strings of symbols. Because users need to remember them, passwords are usually words or phrases of significance to the user. This is an opportunity for the attacker to reduce the search space.

An attacker might steal a password file, or sniff the network segment and capture the user ID/password hash pairs during log-on, and then run a password-cracking tool on them. Because it is impossible to decrypt a hash back to a password, these programs will try a dictionary attack approach first. The program guesses a password; for instance, the word "Dilbert." The program then hashes "Dilbert" and compares the hash to one of the hashed entries in the password file. If it matches, then that password hash represents the password "Dilbert." If the hash does not match, the program takes another guess. Depending on the tool, a password cracker will try all the words in a dictionary, all the names in a phone book, and so on. Again, the attacker does not need to know the original password, just a password that hashes to the same value.

This is analogous to the "birthday paradox," which is an old parlor trick that says, "If you get 25 people together in a room, the odds are better than 50/50 that two of them will have the same birthday." How does this work? Imagine a person meeting another on the street and asking him his birthday. The chances of the two having the same birthday are only 1/365 (0.27 percent). Even if one person asks 25 people, the probability is still low. But with 25 people in a room together, each of the 25 is asking the other 24 about their birthdays. Each person only has a small (less than 5 percent) chance of success, but trying it 25 times increases the probability significantly.

In a room with 25 people, there are 300 possible pairs ($25 \times 24/2$). Each pair has a probability of success of $1/365 = 0.27$ percent, and a probability of failure of $1 - 0.27$ percent = 99.726 percent. Calculating the probability of failure: $99.726 \text{ percent}^{300} = 44$ percent. The probability of success is then 100 percent - 44 percent = 56 percent. So a birthday match will actually be found five out of nine times. In a room with 42 people, the odds of finding a birthday match rise to 9 out of 10. Thus, the birthday paradox is that it is much easier to find two arbitrary values that match than it is to find a match to some particular value.

If the first wave of dictionary guesses fails to produce any passwords for the attacker, the cracking program will try a hybrid approach of different combinations, such as forward and backward spellings of dictionary words, additional numbers and special characters, or sequences of characters. The goal here again is to reduce the cracker's search space by trying "likely" combinations of known words. Note that cracking programs are very clever about guessing hacker jargon; so, do not assume that "h@ck0rz" would be a sufficiently obscure form of "hackers," if that were your password.

After exhausting both of these avenues, the cracking program would start in on an exhaustive or "brute-force" attack on the entire password space. The program also remembers the passwords it has already tried and will not need to recheck these during the search.

Rainbow Tables

An alternative to cracking passwords is simply to know all of them ahead of time. Modern techniques make use of prodigiously large tables that list all possible password hash values and allow quick lookup and retrieval. These are known as rainbow tables. The idea here is that you are trading space for time. You could implement a hash-and-check operation with a very small amount of memory; however, you are at the mercy of your processing speed. Conversely, with enough storage space, you could access a table of every possible hash value for passwords of a given length and on a particular system (for example, all of the older LanMan-type Windows passwords), and then processing speed would be inconsequential. There are techniques for looking up things very quickly in large tables. Computer scientist Philippe Oechslin (2003) demonstrated this at the Crypto 2003 Conference. Using 1.4 GB of data (two CD-ROMs), he showed that he could crack 99.9 percent of all alphanumeric Windows password hashes in 13.6 seconds. Subsequently, Zhu Shuanglei published code and a tool called RainbowCrack that allows anyone to generate his or her own rainbow tables for all sorts of hashing algorithms. There are Web sites where you can download the rainbow tables people have generated using RainbowCrack, and there are various forums where people trade rainbow tables they have custom-generated.

Password-Retrieving Approaches

Before password-cracking can commence, an attacker must first retrieve the password hashes for his program to decipher. Several programs, such as L0phtcrack,¹ have built-in mechanisms to do this. A sophisticated attacker will not try to guess passwords by entering them through the standard user interface, because the time to do so is prohibitive, and most systems can be configured to lock out a user after too many wrong guesses.

On Microsoft Windows systems, obtaining the password hashes requires the "Administrator" privilege to

read them from the database in which they are stored. This is usually somewhere in the system registry. In order to access them, a cracking tool will attempt to dump the password hashes from the Windows registry on the local machine or over the network if the remote machine allows network registry access. The latter requires a target Windows machine name or IP address.

Another method is to access the password hashes directly from the file system. On Microsoft Windows systems, this is the SAM. Because Windows locks the SAM file where the password hashes are stored in the file system with an encryption mechanism known as SYSKEY, it is impossible to read them from this file while the system is running. However, sometimes there is a backup of this file on tape, on an emergency repair disk (ERD), or in the repair directory of the system's hard drive. Alternatively, a user may boot from a floppy disk running another operating system such as Linux and be able to read password hashes directly from the file system. This is why security administrators should never neglect the physical security of systems. If an attacker can physically access a machine, he or she can bypass the built-in file system security mechanisms (see "Bypassing Password Security").

Todd Sabin released a free utility called PWDUMP2 that can dump the password hashes on a local machine if the SAM has been encrypted with the SYSKEY utility that was introduced in Windows NT Service Pack 3 and is also used in Windows 2000 and XP. Once a user downloads the utility, he or she can follow the instructions on the Web page to retrieve the password hashes, load the hashes into a tool such as L0phtcrack, and begin cracking them.

Password Sniffing

Instead of capturing the system user file (SAM on Windows or /etc/passwd or /etc/shadow on UNIX/Linux), another way of collecting user IDs and passwords is through sniffing network traffic. Sniffing uses some sort of software or hardware wiretap device to eavesdrop on network communications, usually by capturing and deciphering communications packets. According to Peiter "Mudge" Zatko (1999), who authored L0phtcrack: "Sniffing is slang for placing a network card into promiscuous mode so that it actually looks at all of the traffic coming along the line and not just the packets that are addressed to it. By doing this one can catch passwords, login names, confidential information, etc."

L0phtcrack offers an "SMB Packet Capture" function to capture encrypted hashes transmitted over a Windows network segment. On a switched network, a cracker will be able to sniff only sessions originating from the local machine or connecting to that machine. As server message block (SMB) session authentication messages are captured by the tool, they are displayed in the SMB Packet Capture window. The display shows the source and destination IP addresses, the username, the SMB challenge, the encrypted LAN manager hash, and the encrypted NT LAN manager hash, if any. To crack these hashes, the tool saves the session and then works on the captured file.

Note that the L0phtcrack application was acquired by Symantec Corporation in 2004. Symantec has since stopped selling this tool to new customers, citing

¹Note that Symantec stopped shipping its L0phtcrack product in March 2006, and stopped supporting it as of December 16, 2006. www.eweek.com/article2/0,1895,1935696,00.asp.

U.S. government export regulations, and announced that they have discontinued support as of the end of 2006 (Narain 2006).

Bypassing Password Security

Limiting physical access to computer systems is still an important way to protect password-enabled systems. Norwegian software developer Petter Nordahl-Hagen developed a tool called “The Offline NT Password Editor” for recovering Windows passwords on workstations. His approach bypasses the NTFS (new technology file system) file permissions of Windows NT, 2000, and XP by using a Linux boot disk that allows one to reset the Administrator password on a system by replacing the hash stored in the SAM with a user-selected hash. His program has even been shown to work on Windows XP systems with SYSKEY enabled. An MS-DOS version also exists, as do versions that boot either from a CD-ROM or USB thumb drive. Thus, physical access to the workstation can mean instant compromise, unless perhaps the system BIOS settings are also password-protected and do not allow a user to boot from floppy or CD-ROM. However, several attacks against BIOS settings have also been published. These include the following (LabMice.net 2003):

- Using a manufacturer’s backdoor password to access the BIOS
- Using password-cracking software
- Resetting the CMOS (complementary metal oxide semiconductor) using the jumpers or solder beads
- Removing the CMOS battery for at least 10 minutes
- Overloading the keyboard buffer
- Using a professional service

Types of Password-Cracking Tools

Password-cracking tools can be divided into two categories—those that attempt to retrieve system-level log-in passwords and those that attack the password-protection mechanisms of specific applications. The first type includes programs such as L0phtcrack, Cain & Abel, and John the Ripper. Some sites for obtaining password-cracking tools for various platforms, operating systems, and applications are included in the “Software Tool References” section at the end of this chapter.

The Russian company ElcomSoft has developed a range of programs that can crack application passwords for Microsoft Office encrypted files, WinZip or PKZip archived files, or Adobe Acrobat (PDF) files. The U.S. government charged ElcomSoft with violating the Digital Millennium Copyright Act of 1998 for selling a program that allowed people to disable encryption software from Adobe Systems that is used to protect electronic books. The case drew attention after ElcomSoft programmer Dmitry Sklyarov was arrested at the DefCon 2001 convention in July 2001. A jury later acquitted Sklyarov and ElcomSoft. Although the jury agreed that ElcomSoft’s product was illegal, they decided to acquit because they believed the company did not mean to violate U.S. law.

PASSWORD SECURITY ISSUES AND EFFECTIVE MANAGEMENT

Enforcing Password Guidelines

The FBI and the Systems Administration and Networking Security (SANS) Institute (2006) maintain a Web page summarizing the “Twenty Most Critical Internet Security Vulnerabilities.” The majority of successful attacks on computer systems via the Internet can be traced to exploitation of security flaws on this list. One of the items on this list is “accounts with no passwords or weak passwords.” In general, these accounts should be removed or assigned stronger passwords.

In addition, accounts with built-in or default passwords that have never been reconfigured create vulnerabilities because they usually have the same password across installations of the software. Attackers will look for these accounts, having found the commonly known passwords published on hacking Web sites or some other public forum. Therefore, any default or built-in accounts also need to be identified and removed from the system or reconfigured with stronger passwords.

With the proliferation of wireless systems, the default configuration vulnerability has become an even bigger issue. For instance, a user who installs a new wireless router at her home and keeps the out-of-the-box settings is susceptible to being compromised. The device will likely have a default service set identifier (SSID), which would attract would-be snoopers because it shows the system has not been customized. Next, after gaining access to the unsuspecting user’s network, the interloper could point his browser to the default network address for configuring the router and use the default UserID/Password that is published on the vendor’s Web site. Within moments, the attacker could have changed the router settings, created a denial of service, or performed other malicious acts because the user never changed her default settings.

The list of common vulnerabilities and exposures (CVEs) maintained by the MITRE Corporation (www.cve.mitre.org) provides a taxonomy for more than 3000 well-known attacker exploits (and some 14,000 others that are currently under consideration). Among these, more than 1100 have to do with password insecurities. The following provides a few examples across many platforms:

- CVE-1999-0366: “In some cases, Service Pack 4 for Windows NT 4.0 can allow access to network shares using a blank password, through a problem with a null NT hash value.”
- CVE-1999-1104: “Windows 95 uses weak encryption for the password list (.pwl) file used when password caching is enabled, which allows local users to gain privileges by decrypting the passwords.”
- CVE-1999-1298: “Sysinstall in FreeBSD 2.2.1 and earlier, when configuring anonymous FTP, creates the ftp user without a password and with/bin/date as the shell, which could allow attackers to gain access to certain system resources.”
- CVE-2000-0267: “Cisco Catalyst 5.4.x allows a user to gain access to the ‘enable’ mode without a password.”

- CVE-2000-0981: “MySQL Database Engine uses a weak authentication method which leaks information that could be used by a remote attacker to recover the password.”
- CVE-2001-0465: “TurboTax saves passwords in a temporary file when a user imports investment tax information from a financial institution, which could allow local users to obtain sensitive information.”
- CVE-2002-0911: “Caldera Volution Manager 1.1 stores the Directory Administrator password in cleartext in the slapd.conf file, which could allow local users to gain privileges.”
- CVE-2003-0601: “Workgroup Manager in Apple Mac OS X Server 10.2 through 10.2.6 does not disable a password for a new account before it is saved for the first time, which allows remote attackers to gain unauthorized access via the new account before it is saved.”
- CVE-2003-0745: “SNMPc 6.0.8 and earlier performs authentication to the server on the client side, which allows remote attackers to gain privileges by decrypting the password that is returned by the server.”
- CVE-2004-0031: “PHPGEDVIEW 2.61 allows remote attackers to reinstall the software and change the administrator password via a direct HTTP request to edit-config.php.”
- CVE-2005-3595: “By default Microsoft Windows XP Home Edition installs with a blank password for the Administrator account, which allows remote attackers to gain control of the computer.”
- CVE-2006-2229: “OpenVPN 2.0.7 and earlier, when configured to use the management option with an IP that is not 127.0.0.1, uses a cleartext password for TCP sessions to the management interface, which might allow remote attackers to view sensitive information or cause a denial of service.”

SANS suggests that to determine whether your system is vulnerable to such attacks, you need to be cognizant of all the user accounts on the system. First, the system security administrator must inventory the accounts on the system and create a master list. This list should include even intermediate systems, such as routers and gateways, as well as any Internet-connected printers and print controllers. Second, the administrator should develop procedures for adding authorized accounts to the list and for removing accounts when they are no longer in use. The master list should be validated on a regular basis. In addition, the administrator should run some password-strength-checking tool against the accounts to look for weak or nonexistent passwords. A sample of these tools is noted in the “Software Tool References” section at the end of this chapter.

Many organizations supplement password-control programs with procedural or administrative controls that ensure that passwords are changed regularly and that old passwords are not reused. If password aging is used, the system should give users a warning and the opportunity to change their passwords before they expire. In addition, administrators should set account lockout policies that lock out a user after a number of unsuccessful log-in attempts, and cause him have his password reset.

Microsoft Windows XP, Server 2003, and Vista include built-in password constraint options in the “Group Policy” settings. An administrator can configure the network so that user passwords must have a minimum length, complexity, minimum and maximum age, and other constraints. It is important to require a minimum age of a password.

Guidelines for Selecting a Strong Password

The following outlines the minimal criteria for selecting “strong” passwords:

- The goal is to select something easily remembered but not easily guessed.
- Length:
 - Windows systems: seven characters or longer
 - UNIX, Linux systems: eight characters or longer
- Composition:
 - Mixture of alphabetic, numeric, and special characters (e.g., #, @, or !)
 - Mixture of upper- and lower-case characters
 - No words found in a dictionary
 - No personal information about the user (e.g., any part of the user’s name, a family member’s name, or the user’s date of birth, Social Security number, phone number, license plate number, etc.)
 - No information that is easily obtained about the user, especially any part of the user ID
 - No commonly used proper names such as local sports teams or celebrities
 - No easily recognized keyboard patterns such as 12345, sssss, or qwerty
 - Try misspelling or abbreviating a word that has some meaning to the user (e.g., “How to select a good password?” becomes “H2sagP?”)

Password Aging and Reuse

Users should be required to change their passwords regularly to limit the usefulness of compromised passwords. Many systems force users to change their passwords when they log in for the first time, and again if they have not changed their passwords for an extended period (say, 90 days). In addition, users should not reuse previous passwords. Some systems support this by recording the old passwords, ensuring that users cannot change their passwords back to previously used values, and ensuring that the users’ new passwords are significantly different from their previous passwords. Unfortunately, such systems usually have a finite memory (say, the past 10 passwords), and users can circumvent the filtering controls by changing their password 10 times in a row until it is the same as the previously used password.

At a predetermined time prior to their password expiration, users should be notified by the system that they will need to change their password. A user who logs in with an ID having an expired password should be required to change the password before further access to the system is permitted. If a password is not changed before the end of its maximum lifetime, the user ID should be locked by

the system, and no log-in should be permitted until a system administrator unlocks it. After a password has been changed, the lifetime period for the password should be reset to the maximum value established by the system.

Social Engineering

Despite advances in technology, the oldest way to attack a password-based security system is still the easiest: coercion, bribery, or trickery against the users of the system. Social engineering is an attack against people, rather than machines. It is an outsider's use of psychological tricks on legitimate users of a computer system, usually to gain the information (e.g., user IDs and passwords) needed to access a system. The notorious "hacker" Kevin Mitnick, who was convicted on charges of computer and wire fraud and spent 59 months in federal prison, told a congressional panel that he rarely used technology to gain information; he used social engineering techniques almost exclusively.

According to a study by British psychologists (Brown 2002), people often base their passwords on something obvious and easily guessed by a social engineer. About 50 percent of computer users base them on the name of a family member, a partner, or a pet. Another 30 percent use a pop idol or sporting hero. Another 10 percent of users pick passwords that reflect some kind of fantasy, often containing some sexual reference. The study showed that only 10 percent use cryptic combinations that follow all the rules of "tough" passwords.

The best countermeasures to social engineering attacks are education and awareness. Users should be instructed never to tell anyone their passwords; doing so destroys accountability. A system administrator should never need to know it either. In addition, users should never write down their passwords. A clever social engineer will find it if it is "hidden" under a mouse pad or inside a desk drawer.

Some Examples of Social Engineering Attacks

"Appeal to Authority" Attack. This is impersonating an authority figure or else identifying a key individual as a supposed acquaintance in order to demand information. For example: A secretary receives a phone call from someone claiming to be the "IT Manager." He requests her user ID and password, or gives her a value to reset her password immediately because "there has been a server crash in the computer center and we need to reset everyone's account." Once she has complied, he now has a valid user ID and password to access the system.

"Fake Web Site" Attack. The same password should not be used for multiple applications. Once a frequently used password is compromised, all of the user's accounts could be compromised. A good social engineering attack might be to put up an attractive Web site with titillating content, requiring users to register a username and password in order to access the "free" information. The attacker would record all passwords (even incorrect ones, which a user might have mistakenly entered thinking of another account), and then use those to attack the other systems frequented by the user. The Web site could even solicit information from the users about their accounts—for

example, what online brokerage, banking, and e-mail accounts they use. Web-site operators can always keep a log of IP addresses used to access the site and could go back to attack the originating system directly.

"Phishing" Attack. Similar to the fake Web site, phishing schemes typically send an official-looking e-mail to the victim informing him about a security problem with his bank or e-mail account, and asking him to reconfirm his personal data via a secure link. The URL appears as if it takes him to the correct Web site, but it actually redirects him to the ISP of the attacker, where the attacker collects his user id, password, and sometimes other private data such as credit card or Social Security numbers.

In 2006, Bank of America implemented a user validation system called SiteKey which was intended to protect people from phishing sites. SiteKey has users enroll by answering a series of challenge/response questions and selecting an image from a gallery. If the user logs on to a Web site purporting to be Bank of America, but he does not recognize his previously chosen picture, he should not proceed. It is likely a rogue site masquerading as the bank (www.bankofamerica.com/privacy/sitekey).

"Dumpster Diving" Attack. Many serious compromises are still caused by contractors and third parties throwing away draft instruction manuals or development notes with user IDs and passwords in them. Social engineers may use "dumpster diving"—digging through paper printouts in the trash looking for such significant information—to gain system access.

Single Sign-on and Password Synchronization

One issue that has irritated users in large secure environments is the increasing number of passwords they have to remember to access various applications. A user might need one password to log in to her workstation, another to access the network, and yet another for a particular server. Ideally, a user should be able to sign on once, with a single password, and be able to access all the other systems on which he or she has authorization.

Some have called this notion of single sign-on the "Holy Grail" of computer security. The goal is admirable—to create a common enterprise security infrastructure to replace a heterogeneous one. It is currently being attempted by several vendors through technologies such as the Open Group's Distributed Computing Environment (DCE), MIT's Kerberos, Microsoft's Active Directory, and public key infrastructure (PKI)-based systems. However, few, if any, enterprises have actually achieved their goal. Unfortunately, the task of changing all existing applications to use a common security infrastructure is very difficult, and this has further been hampered by a lack of consensus on a common security infrastructure. As a result, the disparate proprietary and standards-based solutions cannot be applied to every system. In addition, there is a risk of a single point of failure. Should one user's password be compromised, it is not just his local system that can be breached but the entire enterprise.

Password synchronization is another means of trying to help users maintain the passwords that they use to log

on to disparate systems. In this scheme, when users periodically change their passwords, the new password is applied to every account the user has, rather than just one. The main objective of password synchronization is to help users remember a single, strong password. Password synchronization purports to improve security because synchronized passwords are subjected to a strong password policy, and users who remember their passwords are less likely to write them down.

The following guidelines should be used to mitigate the risk of a single system compromise being leveraged by an intruder into a network-wide attack:

- Very insecure systems should not participate in a password-synchronization system.
- Synchronized passwords should be changed regularly.
- Users should be required to select strong (hard to guess) passwords when synchronization is introduced.

UNIX/Linux-Specific Password Issues

Traditionally, on UNIX and Linux platforms, user information (including passwords) was kept in a system file called `/etc/passwd`. The password for each user is stored as a hash value. Despite the password being encoded with a one-way hash function and a salt as described earlier, a password cracker could still compromise system security if he or she obtained access to the `/etc/passwd` file and used a successful dictionary attack. This vulnerability has been mitigated simply by moving the passwords in the `/etc/passwd` file to another file, usually named `/etc/shadow`, and making this file readable only by those who have administrator (also called “root”) access to the system.

In addition, UNIX or Linux administrators should examine their password file (as well as the shadow password file when applicable) on a regular basis for potential account-level security problems. In particular, it should be examined for:

- Accounts without passwords
- User IDs of 0 for accounts other than root (which are also superuser accounts)
- Group IDs of 0 for accounts other than root (Generally, users do not have group 0 as their primary group.)
- Other types of invalid or improperly formatted entries

Note: Usernames and group names in UNIX and Linux are mapped into numeric forms (UIDs and GIDs, respectively). All file ownership and processes use these numerical names for access control and identity determination throughout the operating system kernel and drivers.

Under many UNIX and Linux implementations (via a shadow package), the command `pwck` will perform some simple syntax checking on the password file and can identify some security problems with it. `pwck` will report invalid usernames, UIDs and GIDs, null or nonexistent home directories, invalid shells, and entries with the wrong number of fields (often indicating extra or missing colons and other typos).

Since 2003, Linux has implemented a security service called “pluggable authentication module” (`pam`), which

governs enforcement of password complexity, including length, and minimum number of upper and lower case letters, digits, and special characters. Whenever a password for a given user ID is set or changed, it is checked versus the configuration settings in `pam_cracklib` to ensure it has the appropriate complexity and does not contain a dictionary word.

Windows-Specific Password Issues

Windows uses two password functions; a stronger one designed for Windows NT and later systems, and a weaker one, the LAN Manager hash, designed for backward compatibility with older Windows 9X networking log-in protocols. The latter is case-insensitive and does not allow passwords to be much stronger than seven characters, even though they may be much longer. These passwords are extremely vulnerable to cracking. There is an article on how to prevent Windows from storing a LAN manager hash of your password in Active Directory and local SAM databases (<http://support.microsoft.com/?id=299656>).

On a standard desktop PC, for example, `L0phtcrack` can try every short alphanumeric password in a few minutes and every possible keyboard password (except for special ALT-characters) within a few days. Some security administrators have dealt with this problem by requiring stronger and stronger passwords; however, this comes at a cost (see “An Argument for Simplified Passwords.” below).

In addition to implementing policies that require users to choose strong passwords, the Computer Emergency Response Team (CERT) Coordination Center provides guidelines for securing passwords on Windows systems (CERT Coordination Center 2003):

- Using `SYSKEY` enables the private password data stored in the registry to be encrypted using a 128-bit cryptographic key. This is a unique key for each system. However, as mentioned in “Bypassing Password Security” above, physical access to the computer and an alternate boot disk can bypass this protection.
- By default, the administrator account is never locked out; so it is generally a target for brute-force log-on attempts of intruders. It is recommended to rename the account in User Manager. It may also be desirable to lock out the administrator account after a set number of failed attempts over the network. The NT Resource Kit provides an application called “`passprop.exe`” that enables Administrator account lockout except for interactive log-ons on a domain controller.
- Another alternative that avoids all accounts belonging to the Administrator group being locked over the network is to create a local account that belongs to the Administrator group, but is not allowed to log on over the network. This account may then be used at the console to unlock the other accounts.
- The Guest account should be disabled. If this account is enabled, anonymous connections can be made to Windows computers.
- The emergency repair disk should be secured, as it contains a copy of the entire SAM database. If a malicious user has access to the disk, he or she may be able to launch a crack attack against it.

How Long Should Your Password Be?

Say you use a typical password of six characters. When you enter this into your computer's authentication mechanism, it is hashed and stored in a database. Because an attacker cannot try to guess passwords at a high rate through the standard user interface (the time to enter them is prohibitive, and most systems can be configured to lock the user out after a consecutive number of incorrect attempts), one may assume that the attacker will get them either by capturing the system password file or by sniffing the network to capture log-in packets.

There are, of course, many other factors to be considered here. What operating system is it? What algorithm is being used for the hash? Is there a salt? What characters will be used for inputting the password? None of these, however, will greatly affect the time needed for brute forcing all possible combinations of passwords. All an attacker really needs is one password to gain entry to a system. If there are 1000 users on the system, he needs only to capture 0.1 percent of the passwords to gain entry.

Nevertheless, let us make an assumption about which characters will be used as input for a password. Each character in a password is a byte. The keyboard has 95 possible choices for each of the six password characters; this makes the password space $95^6 = 735,091,890,625$ combinations.

According to the Web site www.top500.org, several supercomputer clusters in the world can perform in excess of teraflops; that is, a million million floating point operations per second. That is only the publicized machines. It has been conjectured that agencies such as the National Security Agency (NSA) have code-breaking machines that could hash and check passwords at a rate in excess of 1 billion per second, assuming there are 1000 floating point operations required to perform a hash-and-check operation. The actual number, given an elegant implementation, could be somewhat lower than this. Note, as discussed in the "Rainbow Tables" section above, if it is possible to generate a rainbow table for the hashes used in the system, the time to "crack" passwords will be an order of magnitude faster—perhaps only a few seconds. However, many systems, such as Linux, use a salt to randomize the stored password hash. The time-memory trade-off technique used in generating rainbow tables is not practical when this type of hash is used.

How fast could a high-powered attacker check every possible combination of six-character passwords? $735,091,890,625/1,000,000,000 =$ about 12 min (see Table 2).

Keep in mind that this is the time needed to use brute force for every possible combination of passwords. As we said earlier, password crackers will first use dictionary and hybrid attacks before resorting to brute force. Thus, if your password is weak (that is, easily guessed and not sufficiently random), the time to crack it could be much shorter.

What if the system forces users to have a seven-character password? Then it would take the attacker 19 hours to use brute force for every possible password. Many Windows networks fall under this category because of backward-compatibility issues. Passwords on these systems cannot be much stronger than seven characters. Thus, it can be assumed that every password sent on

Table 2: Password Cracking Times of a Mythical Teraflop Supercomputer*

Chars	Combinations	Time to crack (hrs)
0	1	0.0
1	95	0.0
2	9025	0.0
3	857375	0.0
4	81450625	0.0
5	7737809375	0.0
6	735091890625	0.2
7	69833729609375	19.4
8	6634204312890620	1842.8
9	6.E+17	2.E+05
10	6.E+19	2.E+07
11	6.E+21	2.E+09
12	5.E+23	2.E+11
13	5.E+25	1.E+13
14	5.E+27	1.E+15
15	5.E+29	1.E+17
16	4.E+31	1.E+19

*Printable ASCII characters are in codes 32 through 126. ASCII codes 0–31 and 127 are unprintable characters, and 128–255 are special ALT characters that are not generally used for passwords. This leaves 95 printable ASCII characters that are usually used for password generation.

a Windows system using the old LAN Manager hashes could be cracked within a day.

What if the system enforces eight-character passwords? Then it would take the attacker 77 days to use brute-force to obtain them all. If a system's standard policy is to require users to change passwords every 90 days, this would not be sufficient. So, it appears a nine-character password should be sufficient, for today. Fortunately, this is still within the constraints of human memory.

PASSWORD LENGTH AND HUMAN MEMORY

Choosing a longer password does not help much on systems with limitations such as the LAN Manager hash issue. It also does not help if a password is susceptible to a dictionary or hybrid attack. It only works if the password appears to be a random string of symbols, but this type of password can be difficult to remember. A classic study by psychologist George Miller (1956) showed that humans work best with the magic number 7 (plus or minus 2). So it stands to reason that once a password exceeds nine characters, the user is going to have a hard time remembering it.

Here is one idea for remembering a longer password. Security professionals generally advise people never to write down their passwords. But the user could write down half of it—the part that looks like random letters and numbers—and keep it in a wallet or desk drawer.

The other part could be memorized—perhaps it could be a misspelled dictionary word or the initials for an acquaintance, or something similarly memorable. When concatenated together, the resulting password could be much longer than nine characters, and therefore presumably stronger.

Some research has shown that the brain remembers images more easily than letters or numbers. Thus, a number of new schemes use sequences of graphical symbols for passwords. For example, a system called PassFaces replaces the letters and numbers in passwords with sequences or groups of human faces. It is one of several applications that rely on graphical images for the purpose of authentication. Another company, Passlogix, has a system in which users can mix drinks in a virtual saloon or concoct chemical compounds using an onscreen periodic table of elements as a way to log on to computer networks.

AN ARGUMENT FOR SIMPLIFIED PASSWORDS

Using all of the guidelines for a strong password (length, mix of upper and lower case, numbers, punctuation, no dictionary words, no personal information, etc.) as outlined in this chapter may not be necessary after all.

According to security expert and TruSecure Chief Technology Officer Peter Tippet (2001), statistics show that strong password policies only work for smaller organizations. Suppose a 1000-user organization has implemented such a strong-password policy. On average, only half of the users will actually use passwords that satisfy the policy. Perhaps if the organization frequently reminds its users of the policy, and implements special software that will not allow users to have “weak” passwords, this figure can be increased to 90 percent. It is rare that such software can be deployed on all devices that use passwords for authentication; thus, there are always loopholes. Even with 90 percent compliance, this still leaves 100 easily guessed user/ID password pairs. Is 100 better than 500? No, because either way, an attacker can gain access. When it comes to strong passwords, anything less than 100 percent compliance allows an attacker entry to the system.

Second, with modern processing power, even strong passwords are no match for current password crackers. The combination of 2.5-gHz clock speed desktop computers and constantly improving hash dictionaries and algorithms means that, even if 100 percent of the 1000 users had passwords that met the policy, a password cracker might still be able to defeat them. Although some user ID/password pairs may take days or weeks to crack, approximately 150 of the 1000, or 15 percent, can usually be “brute-forced” in a few hours.

In addition, strong passwords are expensive to maintain. Organizations spend a great deal of money supporting strong passwords. One of the highest costs of maintaining IT help desks is related to resetting forgotten user passwords. Typically, the stronger the password (i.e., the more random), the harder it is to remember. The harder it is to remember, the more help desk calls result. Help desk calls require staffing, and staffing costs money. According to estimates from technology analysts such as the Gartner

Group and MetaGroup, the cost to businesses for resetting passwords is between \$50 and \$300 per computer user each year.

So, for most organizations, the following might be a better idea than implementing a strong password policy: Simply recognize that 95 percent of users could use simple (but not basic) passwords—that is, good enough to keep a casual attacker (not a sophisticated password cracker) from guessing them within five attempts while sitting at a keyboard. These could be four or five characters (no names or initials) and changed perhaps once a year. In practical terms, this type of password is equivalent to the current “strong” passwords. The benefit is that it is much easier and cheaper to maintain.

Under this scenario, a system could still reserve stronger passwords for the 5 percent of system administrators who wield extensive control over many accounts or devices. In addition, a system should make the password file very difficult to steal. Security administrators should also introduce measures to mitigate sniffing, such as network segmentation and desktop automated inventory for sniffers and other tools. Finally, for the strongest security, a system could encrypt all network traffic with IPSec on every desktop and server.

Dr. Tippet states: “If the Promised Land is robust authentication, you can’t get there with passwords alone, no matter how ‘strong’ they are. If you want to cut costs and solve problems, think clearly about the vulnerability, threat and cost of each risk, as well as the costs of the purported mitigation. Then find a way to make mitigation cheaper with more of a security impact.”

CONCLUSION

Passwords have been widely used in computing systems since the 1960s, and password security issues have followed closely behind. Now, the increased and very real threat of cyber crime necessitates higher security for many networks that previously seemed safe. Guaranteeing accountability on networks—that is, uniquely identifying and authenticating users’ identities—is a fundamental need for modern e-commerce. Strengthening password security should be a major goal in an organization’s overall security framework. Basic precautions (policies, procedures, filtering mechanisms, encryption) can help reduce risks from password weaknesses. However, lack of user buy-in and the rapid growth of sophisticated cracking tools may make any measure taken short-lived. Additional measures, such as biometrics, certificates, tokens, smart cards, and other means can be very effective for strengthening authentication, but the tradeoff is additional financial burden and overhead. It is not always an easy task to convince management of inherent return on these technologies, relative to other system priorities. In these instances, organizations must secure their passwords accordingly and do the best they can with available resources.

GLOSSARY

Access Control: The process of limiting access to system information or resources to authorized users.

- Accountability:** The property of systems security that enables activities on a system to be traced to individuals who can then be held responsible for their actions.
- ARPANET:** The network first constructed by the Advanced Research Projects Agency of the U.S. Department of Defense (ARPA), which eventually developed into the Internet.
- Biometrics:** Technologies for measuring and analyzing living human characteristics, such as fingerprints, especially for authentication purposes. Biometrics is seen as a replacement for or augmentation of password security.
- Birthday Paradox:** The concept that it is easier to find two unspecified values that match than it is to find a match to some particular value. For example, in a room of 25 people, if 1 person tried to find another person with the same birthday, there would be little chance of a match. However, there is a very good chance that some pair of people in the room will have the same birthday.
- Brute Force:** A method of breaking decryption by trying every possible key. The feasibility of a brute-force attack depends on the key length of the cipher and on the amount of computational power available to the attacker. In password cracking, tools typically use brute force to crack password hashes after attempting dictionary and hybrid attacks to try every remaining possible combination of characters.
- Cipher:** A cryptographic algorithm that encodes units of plaintext into encrypted text (or *ciphertext*) through various methods of diffusion and substitution.
- Ciphertext:** An encrypted file or message. After plaintext has undergone encryption to disguise its contents, it becomes ciphertext.
- Compatible Time-Sharing System:** An IBM 7094 time-sharing operating system created at MIT Project MAC and first demonstrated in 1961. May have been the first system to use passwords.
- Computer Emergency Response Team:** An organization that provides Internet security expertise to the public. CERT is located at the Software Engineering Institute, a federally funded research and development center operated by Carnegie Mellon University. Its work includes handling computer security incidents and vulnerabilities and publishing security alerts.
- Crack, Cracking:** Traditionally, using illicit (unauthorized) actions to break into a computer system for malicious purposes. More recently, either the art or science of trying to guess passwords or copying commercial software illegally by breaking its copy protection.
- Dictionary Attack:** A password-cracking technique in which the cracker creates or obtains a list of words, names, and so on, derives hashes from the words in the list, and compares the hashes with those captured from a system user database or by sniffing.
- Entropy:** In information theory, a measure of uncertainty or randomness. The work of Claude Shannon defines it in bits per symbol.
- Green Book:** The 1985 U.S. Department of Defense CSC-STD-002-85 publication *Password Management Guideline*, which defines good practices for safe handling of passwords in a computer system.
- Hybrid Attack:** A password-cracking technique that usually takes place after a dictionary attack. In this attack, a tool will typically iterate through its word list again, adding certain combinations of a few characters to the beginning and end of each word prior to hashing. This attempt gleans any passwords that a user has created by simply appending random characters to a common word.
- Kerberos:** A network authentication protocol developed at MIT to provide strong authentication for client/server applications using secret key cryptography. It keeps passwords from being sent in the clear during network communications and requires users to obtain “tickets” to use network services.
- Message Authentication Code:** A small block of data derived by using a cryptographic algorithm and a secret key that provide a cryptographic checksum for the input data. MACs based on cryptographic hash functions are known as HMACs.
- Moore’s Law:** An observation named for Intel cofounder Gordon Moore that the number of transistors per square inch of an integrated circuit has doubled every year since integrated circuits were invented. This “law” has also variously been applied to processor speed, memory size, and so on.
- Nonce:** A random number that is used once in a challenge/response handshake and then discarded. The one-time use ensures that an attacker cannot inject messages from a previous exchange and appear to be a legitimate user (see *Replay Attack*).
- One-Way Hash:** A fixed-sized string derived from some arbitrarily long string of text, generated by a formula in such a way that it is extremely unlikely that other texts will produce the same hash value.
- One-Time Password:** Also called OTP. A system that requires authentication that is secure against passive attacks based on replaying captured reusable passwords. In the modern sense, OTP evolved from Bellcore’s S/KEY and is described in RFC 1938.
- Orange Book:** 1983 U.S. Department of Defense 5200.28-STD publication, *Trusted Computer System Evaluation Criteria*, which defined the assurance requirements for security protection of computer systems processing classified or other sensitive information. Superseded by the Common Criteria.
- Password Synchronization:** A scheme to ensure that a known password is propagated to other target applications. If a user’s password changes for one application, it also changes for the other applications that the user is allowed to log on to.
- Phishing:** A play on “fishing”; the idea that bait is thrown out in the hope that some victim will be tempted into biting. In a phishing scheme, an attacker sends an e-mail falsely claiming to be an established legitimate enterprise in an attempt to entice the user into providing private information that will be used for identity theft.
- Plaintext:** A message or file to be encrypted. After it is encrypted, it becomes *ciphertext*.
- Promiscuous Mode:** A manner of running a network device (especially a monitoring device or sniffer) in such a way that it is able to intercept and read every

network packet, regardless of its destination address. Contrast with nonpromiscuous mode, in which a device accepts and reads only packets that are addressed to it.

Rainbow Table: Based on the work of Philippe Oechslin and Zhu Shuanglei, a lookup table that takes advantage of the time-memory trade-off to break passwords. In other words, by listing every possible hash value and providing a quick means for lookup/retrieval, it can break any possible password for a particular system and algorithm.

Replay Attack: An attack in which a valid data transmission is captured and retransmitted in an attempt to circumvent an authentication protocol.

Salt: A random string that is concatenated with a password before it is operated on by a one-way hashing function. It can prevent collisions by uniquely identifying a user's password, even if another user has the same password. It also makes hash-matching attack strategies more difficult because it prevents an attacker from testing known dictionary words across an entire system.

Secure Shell: An application that allows users to log in to another computer over a network and execute remote commands (as in `rlogin` and `rsh`) and move files (as in `FTP`). It provides strong authentication and secure communications over unsecured channels.

Secure Sockets Layer (SSL): A network-session-layer protocol developed by Netscape Communications Corp. to provide security and privacy over the Internet. It supports server and client authentication, primarily for `HTTP` communications. `SSL` is able to negotiate encryption keys as well as to authenticate the server to the client before data are exchanged.

Security Account Manager (SAM): On Windows systems, the secure portion of the system registry that stores user account information, including a hash of the user account password. The `SAM` is restricted via access control measures to administrators only and may be further protected using `SYSKEY`.

Shadow Password File: In `UNIX` or `Linux`, a system file in which encrypted user passwords are stored so they are inaccessible to unauthorized users.

Single Sign-on: A mechanism whereby a single action of user authentication and authorization can permit a user to access all computers and systems on which that user has access permission, without the need to enter multiple passwords.

Sniffing: The process of monitoring communications on a network segment via a wire-tap device (either software or hardware). Typically, a sniffer also has some sort of "protocol analyzer" that allows it to decode the computer traffic on which it is eavesdropping and make sense of it.

Social Engineering: An outside hacker's use of psychological tricks on legitimate users of a computer system to obtain the information (e.g., user IDs and passwords) needed to gain access to a system.

SYSKEY: On Windows systems, a tool that provides encryption of account password hash information to prevent administrators from intentionally or unintentionally accessing these hashes using system registry programming interfaces.

INTRODUCTION

The first concern of classical physical security was to preclude unauthorized access to fixed assets; it did so by enclosing the assets in layers: put the jewels in a safe, in a locked room, in a castle with guards outside, surrounded by a wall and then a moat. A second concern was to maintain the assets in their desired state, protected from fire, flood, wind, mildew, and the like. As time went on, assets became more mobile, and the list of threats grew and became more diverse, including some, such as biological and radiological hazards, that are injurious primarily to people—the most valuable asset to be protected. When the asset is information, there is the further threat that the information may be appropriated and endlessly duplicated even while it remains in place.

The physical assets associated with supporting network operations—storage media, information-processing equipment, facilities, personnel, and transmission media—are not as easy to corral as jewels. Figure 1 illustrates in a “geographic Venn diagram” how these various assets may, in sixteen different combinations, be co-located. Facilities, once the universe of classical physical security concerns, no longer contain all the other assets, viz., the storage media, equipment, and personnel. For example, a company employee may carry beyond company premises storage media within a mobile computing device, as well as crucial personal knowledge capable of supporting or damaging network operations. The transmission media crucial to network operations may reach even where people cannot go, with wireless transmissions reaching virtually everywhere.

Not only has the perimeter to be guarded become more complex and indeterminate, the boundary between physical security and cybersecurity is becoming increasingly blurred. Cybersecurity protects information assets in the form of ones and zeroes against threats that come in the form of other ones and zeroes designed to cause unauthorized changes in or to make unauthorized use of an information asset. A virus is an example of a cyber-threat, and virus-protection software is a corresponding cyberdefense. At some point, physical security ends and cyberdefenses such as encryption must take over. But the classic view (see, for example, Microsoft 2006) that physical security (itself multilayered) forms the “lowest” layer of defense in depth is now a bit simplistic. There are many points at which physical security and cybersecurity work together or converge. A password that should serve as a cyberdefense may be compromised if it is written down. Physical access can be controlled by biometrics and smart-cards. Tracking software can help recover a stolen laptop.

As with cybersecurity, being “equipped” for physical security is not enough—faithful adherence to proper practices is also required. Good behavior cannot replace expensive security equipment, but bad behavior can render that equipment useless. Conduct conducive to physical security begins with the establishment of policies, followed by appropriate education, enforcement, and communication of management’s commitment to the importance of the policies.

Unlike cybersecurity, physical security faces threats to which there are no adequate countermeasures. For instance, although one absolute defense against unauthorized

Figure 1: Co-location of resources

modification of a file by a cyberattack is to store the file on a CD-ROM, we cannot stop a rocket-propelled grenade from destroying the disk; we could preemptively save a backup copy at a distant location, but if an employee is forced at gunpoint to turn it over, any confidential information on it will be irreversibly compromised. This illustrates that, while physical security may be better understood than cybersecurity, maintaining physical security is, in a way, an intractable problem.

That being said, the prevention and mitigation of breaches of physical security are, nevertheless, deserving of investments of money and effort commensurate with the considerable potential benefits. Compromises of confidential customer information (that have come to light) have received much attention, and their financial impact has been analyzed; see, for example, Ponemon Institute (2006) for one study of the cost of data breaches. Given that a single patent-infringement judgment or settlement can run into hundreds of millions of dollars, the theft of trade secrets may easily erase a competitive advantage of comparable magnitude, though such crimes are less likely to receive the attention that accompanies a breach of customer privacy. Even the premature release of information about or the public display of an invention intended to be patented can make it unpatentable in most jurisdictions, regardless of who is responsible for the revelation.

PHYSICAL SECURITY FOR STORAGE MEDIA

Networks exist to provide information and services across a distance. Those information and services depend on

data and computer code, not all of which can reside in active computer memory at all times. Much of it must be saved to nonvolatile storage media at some point.

Magnetic Storage Media

For magnetic storage media such as tapes and disks, the most obvious threat is to the orientation of the ferromagnetic particles within the media. Although physical shocks can partially rearrange particles, a far more common cause for magnetic realignment is, of course, magnetic fields. The Earth's magnetic field, averaging about 0.5 Gauss at the surface, is too weak to cause short-term or even long-term damage to magnetic media. Certain electrical devices pose hazards to magnetic media; among these are electromagnets, motors, transformers, magnetic imaging devices, metal detectors, and devices for activating or deactivating inventory surveillance tags. (X-ray scanners and inventory surveillance antennae do not pose a threat.) Degaussers (bulk erasers) can produce fields in excess of 4000 Gauss, strong enough to affect nearby media not intended for erasure. Although the intensity of most magnetic fields decreases rapidly with distance, to shield against them requires a container made of a metal that is highly permeable (in the sense of being susceptible to magnetization). The container will attract lines of magnetic force, thereby protecting the magnetic media within the container from an external magnetic field. Steel, cobalt, and certain alloys are such metals.

Electrical currents and electrostatic discharge are a related threat to magnetic media. As a precaution against lightning, magnetic media (and sensitive equipment) should be kept away from metal objects, especially structural

Table 1: Temperature Thresholds for Damage to Computing Resources

Component or Medium	Sustained Ambient Temperature at Which Damage may Begin
Flexible disks, magnetic tapes, etc.	38°C (100°F)
Optical media	49°C (120°F)
Hard-disk media	66°C (150°F)
Computer equipment	79°C (175°F)
Thermoplastic insulation on wires carrying hazardous voltage	125°C (257°F)
Paper products	177°C (350°F)

Source: Data taken from National Fire Protection Association (2003, *Standard for the protection of electronic computer/data processing equipment*).

steel and the components of a lightning-arresting system. On the other hand, items within a metal container are protected by the skin effect, so called because the current passes only through the outer skin of the metal.

High temperatures can affect magnetism, but damage to magnetic media occurs at much lower temperatures in the carrier and binding materials. See Table 1.

Arguably the most prevalent threat to removable magnetic media is humidity. Again, the carrier and binding materials are most at risk. Magnetic media deteriorate by hydrolysis, in which polymers “consume” water; the binder ceases to bind magnetic particles to the carrier and sheds a sticky material (which is particularly bad for tapes). Obviously, the rate of decay increases with humidity (and, as for any chemical process, temperature). If condensation forms, the damage is even worse.

The reading of magnetic media can be adversely affected by dirt on the media, but read-write heads for magnetic media typically need to be cleaned far more often than the media that moves by them. However, dirty magnetic tape can actually stick and break. Magnetic tapes that are subjected to repeated reuse (say, for backing up data) should be periodically removed from service to be tested on a tape certifier, which writes sample data to the tape and reads it back to detect any errors; some models incorporate selective cleaning as an option.

For long-term storage of data (e.g., vital statistics and legal records), the guidelines for acceptable humidity, temperature, and temperature changes are far stricter than for ordinary usage. Magnetic media, both tapes and disks, should be stored upright (i.e., with their axes of rotation horizontal) in containers that will not chemically interact with the media. Projected life spans (before any bit reversals) for properly archived magnetic media are considered to be 5 to 10 years for floppy diskettes and 10 to 30 years for magnetic tapes. See International Advisory Committee for the UNESCO Memory of the World Programme (2000) for detailed preservation guidelines.

Optical Storage Media

The first concern with optical media is that they be readable. Any scratches, cracks, dust, or dirt on the bottom

side of a disk (the side facing the laser) will interfere with reading data. CDs are actually more easily damaged by scratching on the seemingly “safe” top side (where a label or marking might appear), since there is very little protecting the data layer from that side. Claims have been made that DVDs’ more robust error-correction schemes (with increased proportion of nondata bits) should, in theory, more than compensate for the increased data density (i.e., increased number of bits effected by a given scratch), making them more forgiving of a scratch than would be a CD. In practice, anecdotal experience of lending libraries seems to indicate that DVDs are more problematic with regard to scratching.

There are commercial products and services for repairing scratched disks by polishing the bottom side. Likewise, there are products for cleaning optical media. Compressed air should not be used to remove dirt, as the resulting drop in temperature produces a thermal shock (rapid temperature change) for the disk.

Although some chemicals can be safely used to clean disks, others can have a detrimental effect on plastics. DVDs seem to be more sensitive to chemicals in the form of markers and label adhesives. If markers are used on the top side, they should be ones designed specifically for chemical compatibility with optical media.

Attached labels are best avoided. A minute off-centering of an attached label may cause instability and, therefore, a greater likelihood of data error. This is more likely with a DVD than with a CD because of the former’s higher rotational speed. The alternative is to use specialized equipment to print labels directly on DVDs.

Optical media can be damaged by bending, even if they appear to return to their original shape, because of microscopic cracking or delamination (separation of layers). Cracks or delamination may also allow the incursion of air and the subsequent deterioration of the reflective layer. In this regard, DVDs are more susceptible to flexing than are CDs; this is because DVDs have protective layers on both sides of the data layer whereas a CD has a single, sturdier protective layer (but little protection on the other side). Hence, DVDs should never be stored in CD cases, as they do not provide adequate support. Furthermore, care should be taken to fully depress the button of the hub

lock before attempting to remove a DVD from its case and to avoid any flexing of the disk.

Both DVDs and CDs should be stored vertically and should not be stored in envelopes (especially ones with plastic windows). See Svensson (2004).

High humidity can result in corrosion of the metallic reflective layer of optical media, especially if there has been any cracking or delamination. High humidity can also promote the growth of mold and mildew, which can obstruct reading from optical media. In tropical regions, there are even documented cases of fungi burrowing into CDs and corrupting data.

Projected life spans for properly archived optical media are considered to be 20 to 30 years. However, since optical media are relatively new, this expectation is extrapolated from accelerated aging tests based on assumptions and end-of-life criteria that may be invalid. Numerous factors other than temperature and humidity influence longevity. Optical media incorporating dyes are also subject to degradation from exposure to light, even at safe temperatures. Write-once formats have greater life expectancies than re-writeable formats. It is known that the bit-encoding dye phthalocyanine (appearing gold or yellowish green) is less susceptible than cyanine (green or blue-green) to damage from light after data have been written.

What appears to be a major determiner of longevity is the original quality of the stored data. This in turn depends on the quality of the blank disk (which can vary greatly), the quality of the machine writing the data, and the speed at which data was written. For example, recording data at a slower speed does not necessarily imply that a better job will be done; lasers calibrated for high-speed recording will “overburn” at a very low recording speed. Actual testing is necessary to ensure that the machine and batch of media being used is producing a good representation of the data. Hartke (1998, 2001) gives an enlightening look at the complexities of this and related issues.

Solid-State Storage Media

Small solid-state forms of removable storage such as USB flash memory are becoming increasingly popular. Although not a major locus of primary or backup storage of information needed for access by a network, removable solid-state storage media may one day take over some of the roles currently played by magnetic and optical media because of the apparently unlimited longevity of information stored in solid-state media.

As the data density of removable storage media increases, so does the volume of information that can be stored on one item and, therefore, the ease with which a vast amount of information can be stolen or misplaced. Small, unattached items are the easiest to lose, either through theft or accident. In the information-processing domain, removable storage media fit this description. Particularly at risk to accidental loss are the tiny solid-state forms of removable storage, such as USB flash memory.

Solid-state memory devices typically have cases that can easily admit water and other foreign substances. Some models of USB flash memory designed for resistance to crushing are now being produced.

Nondigital Storage Media

The loss of more old-fashioned forms of media can still affect operations. For instance, a map of an intranet’s topology may be easier to scan visually from a giant printout than from an electronic version. In some facilities, plastic photographic media such as microfiche still serve a purpose. In some cases, crucial information may have been written down and never stored online. Perhaps more importantly, for any information that is stored in “soft copy” (digitally), there may be a corresponding “hard copy” that could be subject to unauthorized access. This in turn could lead to theft or duplication of the information. In the case of a password written down, a larger breach of network security could result from someone seeing the password, memorizing it, and using it to obtain access to some resource.

As with other media, nondigital storage media may be adversely affected by temperature and humidity. Formation of mold and mildew can damage paper-based records and plastics. Water in particular is a threat to paper documents, the most vulnerable being documents printed with water-soluble inks (the type more commonly used in ink-jet printers). Plastics may further be damaged by heat or light. Paper products actually are more resistant to heat than other forms of storage media (see Table 1).

Physical Access Control for Storage Media

Like most tangible assets, storage media can be stolen. Unlike most assets, information is also subject to theft by copying—the original copy remains, another copy is expropriated—making it a special security challenge. In particular, a person who gains access to storage media of an organization may either copy information from the organization’s media onto his/her own media on site or may temporarily borrow the organization’s media to make a copy elsewhere, retuning it later; in either case, there is likely no intrinsic evidence that the theft by copying took place.

In a later section on “Physical Access Control for Equipment,” a number of strategies are enumerated, some of which could also apply to precluding unauthorized contact with storage media. For now, the discussion will be limited to controlling the physical movement of storage media.

It is self-evident that the extreme physical portability of storage media, especially since the rise of solid-state storage media, works to the disadvantage of those protecting the physical security of those media. Controlling the movement of media owned by an organization can be tracked within a contiguous area physically controlled, for example, by the organization by the use of a radio-frequency identification (RFID) tag. A more “invasive” procedure—such as the use of an x-ray machine, a metal detector, or a manual search—would be needed to prevent the use of untagged media, camera phones, and the like from being brought in by an outsider or an insider to take away a copy of information. The motive of an insider may be benign (perhaps copying information for convenience, not subterfuge), but the result may still pose a potential hazard.

The extreme portability of data may be turned to an advantage, in the case of mobile devices, such as laptop

computers. If the loss of information within a computer is more devastating than the loss of the computer itself, one approach to safeguarding information is to “sacrifice” hardware but preserve the confidentiality of information by storing data only on removable storage media so that theft of the machine from a vehicle or room will not compromise the data. There are several problems with this. First, it may be difficult to ensure that no remnant of the data is stored with or within the device, as operating systems may create “echoes” of files. If there really is no copy of a file on a machine, then the machine is removed as a locus of backup data.

The smallness that makes portable media so convenient to carry also makes them easy to lose. To counter this, some versions have been worn as a necklace or incorporated in larger items such as pens, watches, and Swiss Army knives, which makes them a little harder to misplace.

Storage Media Disposal and Reuse

At some time, every piece of storage media of every type will cease to play its current role. It may be reused to store new information, it may be recycled into a new object, or it may be “destroyed” in some sense (probably not as thoroughly as by incineration). If it is to be used by another individual not authorized to access the old information stored within it, the user of that information may very well think to purge the information. If it is to be “recycled” or “destroyed,” its original user may assume that no attempt to access the old information will be made after it leaves his or her possession. This is a foolhardy assumption.

The term *dumpster diving* usually refers to an outsider pillaging items that have been “thrown out” and are no longer in a secure area, although perhaps still on an organization’s property. (The legal remedies with respect to dumpster diving will depend on local laws, legal precedents, and especially the circumstances under which an item was discarded and recovered.) However, a similar threat to data confidentiality can come from an insider scrounging within a trash receptacle within a building for discarded documents, media, and equipment to recover information. At the other extreme, recovery could, in theory, take place thousands of miles from the point at which an object was initially discarded. A large fraction of the purportedly “recycled” components from industrialized countries actually end up in trash heaps in Third World countries. Thus, media must be carefully sanitized regardless of whether it is to be reused or discarded. The only difference is that care must be taken not to damage the media in the former case.

For magnetic media, it is fairly well known that “deleting” a file really only changes a pointer to the file; the ones and zeroes of the file remain unchanged. There are commercial, shareware, and freeware tools for overwriting files so that all the bits are replaced with, for example, all ones, then all zeroes, than random bits. Echoes of the original information may remain in other system files, however. Another potential problem is that sectors that have been flagged as bad might not be susceptible to overwriting. Special, drive-specific software should be used to overwrite hard drives because each has its own way of using hidden and reserved sectors.

Even after all sensitive bytes have been overwritten by software, there may still be recoverable data, termed “magnetic remanence.” One reason is that write heads shift position over time so that where new bytes are written does not perfectly match where the old bytes were written. Hence the use of a degausser is generally recommended. Some models can accommodate a wide range of magnetic media, including hard drives, reel or cartridge tape, and boxed diskettes. Degaussers are rated in Gauss (measuring the strength of the field they emit), in Oersteds (measuring the strength of the field within the media they can erase), or in dB (measuring on a logarithmic scale the ratio of the remaining signal to the original signal on the media). A degausser generates heat rapidly and cannot be operated continuously for long periods; it should be equipped with an automatic shutoff feature to prevent overheating. Even degaussing may leave information retrievable by an adversary with special equipment. If a hard drive is not to be reused, then grinding off the surface is an option. For more information on magnetic remanence, see National Computer Security Center (1991).

Guidelines for sanitizing write-once or rewritable optical media are not as clear. In theory, even write-once disks can be overwritten. But from what has been said about magnetic media, it is inadvisable for any optical media to be erased for reuse. Two “folk remedies,” breaking the disk or placing it in a microwave oven for two seconds, should not be used. Another suggestion, scratching, may be ineffective because there are commercial products and services for repairing scratched disks by polishing. Therefore, if complete destruction of the disk is not possible, it should be ground to the point of obliterating the layer on which the data are actually stored.

For printed media holding sensitive information, reuse is not an option. Some shredders are worthless, slicing pages into parallel strips, which can be visually “reassembled.” At the other extreme is government equipment that liquefies documents to the point at which they cannot be recycled (because the paper fibers are destroyed). In between are crosscut shredders that produce tiny pieces of documents, a reasonable approach.

An increasingly common practice is for an organization to outsource their shredding to a company specializing in document disposal. It goes without saying that the organization is now dependent on the honesty and competence of the document disposal company. Moreover, documents destined to be picked up by the document disposal company are often deposited by organization personnel in centrally located boxes. The security of such a box, particularly if documents remain there overnight (as is often the case), may be questionable. The construction may involve flimsy materials and locks, and the slot for allowing the insertion of documents may also allow retrieval of them if they stack up high enough within the boxes.

Regardless of whether shredding is handled internally or outsourced, some personnel choose to accumulate sensitive documents in containers or in piles on desks with signage indicating “To be shredded.” This is an example of counterproductive security signage; to an attacker, the translation is: “This is the good stuff!”

For maximum security in reusing or disposing of media, learn to think forensically. If a government agency

could recover information from your media, so could a sufficiently sophisticated adversary.

Redundancy of Storage Media

Redundancy is the safety net for ensuring integrity and availability of resources. Confidentiality, on the other hand, cannot be “backed up”; some damage, such as the revelation of personal information, can never be repaired. Redundancy can be viewed as a preventive measure in that it prevents a permanent or extended loss of information and/or services. In fact, redundancy only pays dividends when other defenses have failed to prevent some calamity. In that sense, exploiting redundancy is a reactive measure. Redundancy cannot succeed without a combination of foresight and discipline. An organization must envision the potential need for redundancy and must consistently adhere to proper practices.

Perhaps the first type of redundancy that springs to mind is to back up data. If only a single copy of information exists, it may be difficult, if not impossible, to reconstruct it with complete confidence in its validity. Not to be overlooked are system software and configurations and any documents needed to restore systems expeditiously.

There are a wide variety of schemes for creating backups. Many are based on some type of high-density tape. Capacities for some are measured in terabytes. The backup procedure can be either manual or automated. However, the former approach is subject to human error or simple neglect. The latter approach is safer, but should issue a notification if it encounters problems while performing its duties. Backups can be made, managed, and used remotely. Some systems allow access to other cartridges while one cartridge is receiving data. Reliability and scalability are important features to consider when choosing a system. As mentioned earlier, tapes that are subjected to repeated reuse should periodically be tested and, if necessary, cleaned by a tape certifier.

Ideally, backups should be kept far enough away from the site of origin that a single storm, forest fire, earthquake, or dirty bomb could not damage both locations. At a bare minimum, backups should be kept in a safe that is fireproof, explosion-resistant, and insulated so that heat is not conducted to its contents. Backups that are going off-site (perhaps via the Internet) should be encrypted. In all cases, access to backups should be restricted to authorized personnel.

Point-in-time recovery requires not only periodic backups but also continual logging of changes to the data since the last complete backup so that files can be reconstructed to match their most recent version. Although the need to back up digital information is well recognized, essential printed documents are sometimes overlooked. These can be converted to a more compact medium (e.g., microfiche).

See also “Backup and Recovery System Requirements” for more details.

Time

Time is the enemy of all things made by humans, and stored information is no exception. Time is the ally of all

threats that have hidden, cumulative effects, especially inappropriate temperature and humidity. As has already been discussed, even atmospheric conditions that would be acceptable for day-to-day storage and usage of media in the short run will degrade media of all types in the long run. All archived data of critical importance should be sampled periodically and backed up well before the rate of correctable errors indicates that data might be unrecoverable at the next sampling.

Although the physical degradation of information has been around since the days of cave art, a new threat has emerged now that the Information Age is decades old: technological obsolescence. Even physically perfect data has been effectively lost because it outlived the software or hardware needed to read it. Successive generations of information storage technology have resulted in data lost because no one thought to convert the data to a new format when the hardware, supporting software, or human expertise associated with the old storage format faded into oblivion. Therefore, before its storage format becomes obsolete, the data must be converted to an actively supported format.

Official records of births, deaths, marriages, legal proceedings, and transfers of property ownership, all of which should obviously be kept in perpetuity, are easy to keep in mind when a new storage format comes along; although the costs of converting to the new format may be high, there are always benefits in terms of storage space, access time, and possibly searching capabilities. Data gathered for other reasons, perhaps as part of a scientific or socioeconomic study, are very susceptible to eventual loss because of (temporary) disinterest. Human knowledge often follows a waterfall model, dropping from current/interesting to outdated/uninteresting to archaic/irretrievable. In many cases, the old information then becomes of interest again, precisely because it *is* old. Unfortunately, it is not always possible to anticipate which information will someday be useful, perhaps after being ignored for several techno-generations.

PHYSICAL SECURITY FOR INFORMATION-PROCESSING EQUIPMENT

Equipment for processing information has certain physical requirements for its continued (unimpaired) functioning. These include an appropriate supply of basic utilities (electrical power, telecommunications services, and water) and an environment free of inappropriate temperature, humidity, substances, and forces.

Physical security must not only ensure the availability of the equipment for legitimate use, but must also control physical access to the equipment to guard against damage, theft, and unauthorized usage of it.

Utilities

Sustaining information requires electrical power, telecommunication services, and water. In most cases, an organization is at the mercy of one or more external agencies for these utilities. Each agency may be a cooperative venture, may be directly controlled by a government, may

be a corporate monopoly operating with government oversight, or may be one among many competing companies. The dependability of these agencies and the likelihood of interruptions due to forces of nature vary widely from region to region, even from neighborhood to neighborhood. Some elements of the world's infrastructure—roads, bridges, railroads, and buildings—age in ways obvious to the casual observer. Others, such as water, sewer, telecommunications, and electrical networks, age more invisibly and often receive less attention as a result. In the United States, deregulation of and competition among electric companies has fostered the unwillingness of companies to upgrade transmission capacity that can be used by its competitors.

Municipal

Obviously, a complete loss of municipal power (discussed earlier) precludes the operation of electrical devices and causes the loss of any information stored in volatile memory. Although a few electrical utilities are “islands,” most are tied into a massive grid. The conundrum is this: The large, interconnected networks fashioned to allow power demands to be met by sharing power resources are precisely the same thing that allows one mountain climber to bring down all the other climbers roped together. The year 2003 brought reminders of this when a massive power outage in North America affecting 50 million people was followed soon afterward by blackouts in the United Kingdom and Italy. Many had thought power disruptions on this scale were no longer a threat. In fact, the strain placed on the world's aging electrical systems seems only to worsen.

In the case of the North American blackout, human errors have been well documented as a contributing factor. (See U.S.-Canada Power System Outage Task Force 2004.) Obviously, human error will never be eliminated; utilities can only strive to prevent, catch, or compensate for such errors. Perhaps the most important lesson to be learned is that there will always be some new combination of circumstances that may fall outside the range of what the best system can handle. Deliberate sabotage, either by physical or computer attack, has long been feared as a possibility. Certainly, there are many natural events that can cause power failures on a variety of scales regardless of the system, including the following:

- ice storms and snow storms
- wind storms (including tornadoes and hurricanes)
- earthquakes
- fires
- solar flares (see the section on “Electromagnetic Interference,” below)

A generalization that can be made is that large-scale outages tend to take longer to fix and, therefore, produce even more bad consequences. One is that battery-based backup power supplies (discussed below in the section on “Uninterruptible Power Supply”) are more likely to fail before power is restored. If the outage lasts days, even backup generators may run out of fuel if it must be pumped from holding tanks to delivery trucks; generators

fueled by piped-in natural gas are less susceptible to such a problem.

There is, of course, no guarantee that a continuous supply of backup power will be enough to weather a widespread blackout. Just getting to work may be a challenge for employees who normally depend on electric trains or traffic signals. Therefore, it may be necessary to house critical employees on-site. Even if one company has done its part to stay operational, its continued functioning may be impossible or moot if another company has not had the same foresight.

Telecommunications Service

By definition, telecommunications service of some sort is an essential part of any computer network. Loss of telecommunications capabilities effectively nullifies any facility whose sole purpose is to provide information and service to the outside world. Although maintaining connectivity to perform that role is the highest priority, maintenance of communications for voice and for external notification of alarm conditions is still necessary to support that role.

A telecommunication difficulty may originate internally or externally. In the latter case, an organization must depend on the problem-solving efficiency of another company. In situations in which voice and data are carried by two separate systems, each is a possible point of failure.

Despite the interconnected nature of telecommunication systems, problems typically do not cascade the way electrical problems do. Hence, they rarely strike an entire system. The exceptions (e.g., the loss of all toll-free service by one phone company) have tended to be the result of a software problem. On certain holidays (for example Mother's Day in the United States), a spike in the number of calls taxes transmission capacity.

Regional disruptions in telecommunications service can result from weather, at the surface or in space. It is not uncommon for large areas to experience lines downed by wind or ice storms. Satellite dishes may be damaged by wind or rendered temporarily inoperable by a thick blanket of snow or ice. Solar flares (discussed below) can affect satellite and radio communications, especially at high latitudes. A widespread disruption of Internet service in 2001 resulted from such a train derailment and ensuing fire in a tunnel in Baltimore.

On a local scale, service disruptions are frequently due to underground lines being accidentally dug up by construction workers. In local emergencies, phone lines typically become clogged, and this can have a ripple effect as calls are rerouted. This applies even to cellular communications. Or cellular services could be shut down, as occurred on September 11, 2001, for fear they might be used to trigger bombs (a technique used 2½ years later in Madrid).

Whereas the robustness of an intranet is often under an organization's own control, communication beyond a single campus typically depends on an Internet service provider (ISP). Politically, operationally, and economically, it may make sense to have a single ISP. From the standpoint of robustness, however, it is better to have at least two service providers and to have their respective cables exit the organization's physical perimeter by different routes (so that any careless excavation cannot

damage both lines). Internally, the organization must be able to switch critical services promptly from one provider to the other.

Less glamorous but also essential is basic voice communication. Even if network communication is entirely internal to an organization and not dependent on an external provider of telecommunication services, the physical security of that internal network does not stop at the door. Events outside—riots, dust storms, rolling brownouts—can disturb operations inside. Physical security policies must provide for timely, two-way flow of information (e.g., monitoring of weather forecasts and prompt reporting of internal incidents to relevant authorities). Increasingly, voice communication may be handled by VoIP (voice over Internet protocol). Thus, a lack of Internet service automatically implies a lack of voice communication, a fact to be taken into consideration when weighing the benefits of VoIP.

Phone service is a resource that may be misappropriated on a large scale (as opposed to the occasional personal phone call). Although less common now, some types of PBX (private branch exchange) can be “hacked,” allowing an attacker to obtain free long-distance service or to mount modem-based attacks from a “spoofed” phone number.

As already mentioned, cellular communications may also fail in an emergency. Another alternative emergency communication system would be a battery-powered, two-way radio that broadcasts on a frequency monitored by emergency agencies; this may require a governmental license. In any case, RF-emitting devices must not be active near equipment that could suffer from the emissions. Chapter 12 of Garcia (2001) discusses the use of radios as a standard tool of security guards and suggests a minimum of four to six channels as a defense against jamming.

Water

Although water is often looked on as a threat to computer network equipment, the lack of water can also be a threat. As was the case with storage media, information-processing equipment will suffer from excessively high temperatures. In some facilities, heating, ventilation, and air conditioning (HVAC) equipment is an essential support component for information-processing equipment. After the attack on the Pentagon, the maintenance of computer operations hinged on stopping the hemorrhage of chilled water used for climate control.

Water is also required for human sanitation needs and for many fire-suppression systems, even in areas with sensitive equipment (as will be detailed later).

Electrical Anomalies

As discussed earlier, electrical equipment cannot function without power, but the quantity and quality of electricity supplied to equipment are important, too. The term *power conditioning* refers to smoothing out the irregularities of the power supply. Although maintaining power is clearly the highest priority, we introduce power conditioning first, as power maintenance devices can also condition power.

Electrical anomalies that affect equipment need not arrive via the power supply. Others result from the buildup and discharge of static electricity. Still others arise when one electrical device broadcasts “information” in conflict with the digital information being processed by another device.

Power Conditioning

Low-voltage equipment such as telephones, modems, and networks are susceptible to small changes in voltage. Integrated circuits operate on very low currents (measured in milliamps); they can be damaged by minute changes in current. Power fluctuations can have a cumulative effect on circuitry over time, termed “electronic rust.” Of the data losses due to power fluctuations, about three-fourths of culpable events are drops in power.

Even under normal conditions, the power grid will deliver transients created as part of the continual balancing act performed in distributing power. Abnormalities in the power supply are also caused by loose connections, wind, tree limbs, and errant drivers. Another source of surges is lightning; even cloud-to-cloud bolts can induce voltage on power lines.

Both the power grid and communications can be affected by so-called space weather. The Earth’s magnetic field captures high-energy particles from the solar wind, shielding most of the planet while focusing it near the magnetic poles. Communications satellites passing between oppositely charged “sheets” of particles (seen as the Aurorae Borealis and Australis) may suffer induced currents, even arcing; one was permanently disabled in 1997. A surge (sudden increase in current) due to a 1989 geomagnetic storm blew a transformer, which in turn brought down the entire HydroQuébec electric grid in 90 seconds. The periods of most intense solar activity generally coincide with Solar Max, when the cycle of sunspot activity peaks every 10.8 years (on the average). The most recent peak was in July 2000. That said, some of the largest flares ever recorded occurred in October 2003 (and did adversely affect air-traffic control at high latitudes). It should be noted that the span of recorded history of solar weather disrupting human activity is very short; a solar anomaly of unprecedented scale could blow out transformers at all latitudes.

Although external sources are the obvious culprits, the reality is that most power fluctuations originate within a facility. A common circumstance is when a device that draws a large inductive load is turned off or on; thermostatically controlled devices, such as fans and compressors for cooling equipment, may turn off and on frequently.

Surge protection ideally has three layers: lightning arresters, circuit breakers, and surge protectors and/or line filters. Uninterruptible power supplies can also provide surge protection.

Lightning Precautions. The most devastating form of power surge is from a direct or nearby lightning strike. In addition, the heat from lightning can ignite a fire or can physically destroy by explosive expansion. But few businesses would be willing to disconnect from the municipal power supply whenever the potential for lightning exists. Nor would that prevent all problems. Lightning can be

surprisingly invasive, penetrating where rain and wind do not. In addition to direct hits on power lines or a building, near misses can travel through the ground and enter a building via pipes, telecommunication lines, or nails in walls. Moreover, lightning does not always hit the most “logical” target, and it can arrive unexpectedly.

Consequently, the first line of defense for a large building should be a lightning protection system. Although properly a defense applied at the level of facilities, it is discussed here because of its relation to surge protection. See National Fire Protection Association (2000, *Standard for installation of lightning protection systems*) and International Electrotechnical Commission (1993) for different viewpoints on lightning protection systems.

For homes, there are surge protectors for power, telephone, and cable TV lines; however, during an electrical storm, there is no substitute for disconnecting computers from both the electric grid and communication lines.

Surge Protectors and Line Filters. A surge protector is designed to protect against sudden increases in current. Ideally, it forms a third line of defense, the circuit breaker being the second, and a lightning protection system the first.

Surge protectors are currently based on four technologies, described in Table 2.

Metal oxide varistor (MOV), gas tube, and silicon avalanche diode (SAD) surge protectors short-out the surge and isolate it from the protected equipment. The reactive-circuit type uses a large inductance to spread a surge out over time. All should have lights to indicate whether they are in functioning order. MOVs and SADs are the types preferred for computing environments because of their reaction times. All surge protectors require a properly grounded electrical system in order to do their job.

Line filters clean power at a finer level, removing electrical noise entering through the line power. Their concern is not extreme peaks and valleys in the alternating current (AC) sine wave, but modulation of that wave. Their goal is to restore the optimal sine shape. Power purity can also be fostered by adding circuits rather than filters. The most important precaution is to keep large machinery off any circuit powering computing equipment. If possible, it is preferable to have each computer on a separate circuit.

Uninterruptible Power Supply (UPS)

An uninterruptible power supply counteracts a loss of power for equipment whose continued functioning is crucial. Often forgotten is that power supply is also crucial for support equipment, such as HVAC and some types of monitoring devices. For some equipment, power may need to be maintained only long enough for a graceful shutdown without loss of data.

An uninterruptible power supply typically provides surge protection as well as power continuity. This is accomplished by means of separate input and output circuits, the input circuit inducing current in the output circuit. A UPS may also incorporate noise filtering. UPS systems fall into three categories.

An online system separates the input and output with a buffer, a battery that is constantly in use and (almost) constantly being charged. This is analogous to a water tank providing consistent water pressure, regardless of whether water is being added to it. This is the original and most reliable design for a UPS. In the strictest sense, this is the only truly uninterruptible power supply; its transfer time (defined below) is 0 msec.

An offline system sends the primary current straight through in normal circumstances, but transfers to backup power if its detection circuit recognizes a problem with the primary power. The problem might be a complete drop in primary power, but it might also be a spike, a surge, a sag (drop in voltage), or electrical noise.

A line interactive system is similar to an offline system, but its output waveform will be a sine wave (as is the input waveform) rather than a square or step wave. Aside from its basic type, the most important characteristics of a UPS are its

- capacity—how much of a load it can support (measured in volt-amps or watts)
- voltage—the electromotive force with which the current is flowing (measured in volts)
- efficiency—the ratio of output current to input current (expressed as a percentage)
- backup time—the duration during which it can provide peak current (a few minutes to several hours)
- transfer time—the time from the drop in primary power until the battery takes over (measured in milliseconds)

Table 2: Comparison of Types of Surge Protectors

Surge Protector Type	Characteristics
MOV (metal oxide varistor)	Inexpensive, easy to use, but progressively degrades from even minor surges (possibly leading to a fiery demise)
Gas tube	Reacts quickly, can handle big surges, but may not deactivate until an alternating circuit polarity flip (which may mean the computer shuts down in the meantime)
SAD (silicon avalanche diode)	Faster than an MOV (1 nsec vs. 5 nsec), but has a limited power capacity
Reactive circuit	Also smoothes out noise but can only handle normal-mode surges (between hot and neutral lines) and may actually cause a common-mode surge (between neutral and ground lines), which is thought to be the more dangerous type of surge for desktop computers

- battery life span—how long it is rated to perform as advertised;
- battery type—a small Ni-MH (nickel metal hydride) battery may support an individual machine, whereas lead-acid batteries for an entire facility may require a room of their own
- output waveform—sine, square, or step (also known as a modified sine) wave

Another consideration is the intended load: resistive (as a lamp), capacitive (as a computer), or inductive (as a motor). Because of the high starting current of an inductive load, the components of an offline UPS (with its square or step wave output) would be severely damaged. Actually, an inductive load will have a similar but less severe effect on other types of UPS systems (with sine-wave output).

Some UPS systems have features such as scalability, redundant batteries, or redundant circuitry. Especially important is interface software, which can do any or all of the following:

- indicate the present condition of the battery and the main power source
- alert users when backup power is in operation, so that they can shut down normally
- actually initiate a controlled shutdown of equipment prior to exhaustion of backup power

This last feature is critical on those occasions (e.g., fires and floods) when power must suddenly be cut; this includes disconnecting a UPS from its load. (Emergency lighting and fire detection and suppression systems must, of course, have self-contained power sources and remain on.) Any intentional disruption of power should be coordinated with computers via software to allow them to power down gracefully.

The existence of any UPS becomes moot whenever someone accidentally flips the wrong switch. The low-cost, low-tech deterrent is switch covers, available in stock and custom sizes.

Large battery systems may generate hydrogen gas, pose a fire hazard, or leak acid. Even a sealed, maintenance-free battery must be used correctly. It should never be fully discharged, it should always be recharged immediately after use, and it should be tested periodically.

Many UPS systems have backup times designed only to allow controlled shutdown of the system so that no data are lost and no equipment is damaged. For continued operation during extended blackouts, a backup generator system will also be necessary. It is tempting to place large UPS systems and generators in a basement, but that can backfire if the power outage is concurrent with water entering the building. It is important to anticipate plausible combinations of calamities.

A UPS should come with a warranty for equipment connected to it. However, the value of any lost data is typically not covered.

When limited resources do not allow for all equipment to be on a UPS, the process of deciding which equipment is most critical and therefore most deserving of guaranteed power continuity should consider two questions. First,

if power is lost, will appropriate personnel still receive automated notification of this event? Second, is the continued functioning of one piece of equipment moot if another component loses power?

See Kozierok (2004) for a sequence of Web pages introducing the various aspects of the subject.

Electrostatic Discharge

A type of electrical anomaly worthy of special note can be created on a very local scale. Triboelectricity (static electricity) results from the same segregation of positive and negative charges that spawns lightning. It typically is generated by friction. Among factors contributing to a static-prone environment are low relative humidity (possibly a consequence of heating) and synthetic fibers in floor coverings, upholstery, and clothing. Even when not discharged, static electricity poses a risk because it can attract contaminants.

An electrostatic discharge (ESD) of static electricity, though highly localized, is nevertheless a potentially serious form of excess power. It can produce electromagnetic interference (see the next section) or a spike (momentary increase in voltage) of surprisingly high voltage. Especially at risk is integrated circuitry that has been removed from its antistatic packaging just before installation. In actuality, just opening the cover of a computer increases the vulnerability of the components inside. Estimates on the voltage threshold at which damage to electronic circuitry can occur vary by an order of magnitude—not surprising given the variety of circuits in use. Intel (2003) says, “Many of the more sophisticated electronic components can be damaged by charges as low as 10 volts.” Next-generation technology in development will be even more sensitive to discharges. At a few thousand volts, monitors, disk drives, and printers can malfunction and a computer system may shut down.

There is more agreement on voltage thresholds that relate to human perception. The minimum voltages at which a discharge can be felt and heard are in the ranges of 1500 to 3000 and 3000 to 5000 volts, respectively. Humans can generate over 10,000 volts, enough to produce a visible blue spark. The point is this: The most likely delivery system for a discharge is a human, and a human may deliver a charge that is both damaging and imperceptible. See Electrostatic Discharge Association (2001) for a thorough introduction to ESD.

The dangers of static electricity can be reduced by inhibiting its buildup, providing ways for it to dissipate gradually (rather than discharge suddenly), or insulating vulnerable items. General techniques for discouraging the buildup of static electricity include the following:

- Properly bond components and ground equipment.
- Keep the relative humidity from dropping too low (i.e., below 40 percent).
- Avoid the use of carpets and upholstery with synthetic fibers, or spray them with antistatic sprays.
- Use antistatic tiles or carpets on floors.
- Do not wear synthetic clothing and shoes with soles prone to generating charges.

- Use an ionizer, which sends both positive and negative ions into the air as a neutralizing influence.

It is also advisable to keep computers away from metal surfaces or to cover metal surfaces with dissipative mats or coverings.

Electronic circuitry becomes exposed to a possible ESD from a human as soon as the case of a computer is open. It is most at risk when it is encased in neither a computer nor its antistatic shipping container. The following precautions should be taken when installing integrated circuits and cards:

- Work on an antistatic mat.
- Use an antistatic “garment” such as a bracelet or strap for wrists and ankles, glove, finger cot, or smock.
- Attach the computer, antistatic mat, and antistatic garment to a common, reliable ground.
- Avoid touching any conducting surface of a card or chip.
- Do not set a component on a synthetic or other static-prone surface.

See Electrostatic Discharge Association (2001) for a sequence of Web pages introducing ESD and its control.

Electromagnetic Interference

Digital and analog information is transmitted over conductive media by modulating an electrical current or is broadcast by modulating an electromagnetic wave. Even information intended to remain within one device, however, may become electromagnetic interference (EMI) for another device. Any energized wire emits electromagnetic radiation, and any wire (energized or not) can act as an antenna. Thus, electrical devices have an inherent potential to interfere with one another by broadcasting and receiving conflicting “information.” The “messages” may have no more meaning than the “snow” on a television screen. Even with millions of wireless communications devices on the loose, much of the “electromagnetic smog” is incidental, produced by devices not designed to broadcast information.

The terms EMI and RFI (radio-frequency interference) are used somewhat interchangeably. The term electrical noise usually indicates interference introduced via the power input, though radiated energy may have been among the original sources of the noise; this term is also used with regard to small spikes. EMC (electromagnetic compatibility) is a measure of a component’s ability neither to radiate electromagnetic energy nor to be adversely affected by electromagnetic energy originating externally. Good EMC makes for good neighbors. The simplest example of incompatibility is cross talk, when information from one cable is picked up by another cable. By its nature, a digital signal is more likely to be received noise-free than an analog signal.

EMI from natural sources is typically insignificant (background radiation) or sporadic (like the pop of distant lightning heard on an amplitude-modulated radio). Occasionally, solar flares can muddle or even jam radio communications on a planetary scale, especially at Solar

Max. Fortunately, a 12-hour window for such a disruption can be predicted days in advance. It is now possible to receive automated alerts regarding impending adverse space weather—that is, electromagnetic anomalies originating with solar flares and potentially disruptive of communications and power networks (especially at high latitudes). The service can be tailored with regard to the means of notification (e-mail, fax, or pager), the type of event expected (radio burst, geomagnetic impulse, and so forth), and the threshold at which a warning should be reported. See Space Environment Center (2002).

Most EMI results from electrical devices or the wires between them. Modulating power supply lines to synchronize wall clocks within a facility can have the side effect of interfering with the proper functioning of computer systems. For radiated interference, mobile phones and other devices designed to transmit signals are a major hazard; according to Garfinkel (2002), they have triggered explosive charges in fire-extinguisher systems. Major high-voltage power lines generate fields so powerful that their potential impact on human health has been called into question. Motors are infamous sources of conducted noise, although they can radiate interference as well.

Government regulations limit how much RF (radio-frequency) radiation computers and other electronic devices may emit and where they may be used. To achieve EMC in components, there are specially designed, conductive enclosures, gaskets, meshes, pipes, tapes, and sprays. The simplest measure for achieving EMC is to use shielded cables and to keep them separated to prevent cross talk. Devices designed to be RF emitters, such as mobile phones, should be kept away from computers with sensitive data.

For an annotated bibliography of EMC publications, see Gerke (2003). An especially important reference regarding grounding and EMC is Institute of Electrical and Electronic Engineers (1999).

On a related note, some equipment can also be damaged by strong magnetic fields.

Environmental Conditions

As with storage media, the physical security of network equipment includes maintaining an environment free of inappropriate temperature, humidity, substances, and forces.

Temperature and Humidity

Most individual pieces of electrical equipment have no control over humidity and possess merely a fan for temperature control. Thus, in many facilities, dedicated HVAC (heating, ventilation, and air-conditioning) equipment is an essential support component for maintaining the security of information. As mentioned earlier, after the attack on the Pentagon, continued computer operations hinged on stopping the hemorrhage of chilled water for climate control. Because HVAC systems generally serve rooms and buildings rather than individual pieces of equipment, discussion of HVAC will be deferred until the major section on facilities. For now, the focus is primarily on the threats to equipment.

Most electrical equipment is designed for use at low to moderate humidity. High humidity has a long-term

corrosive effect. On the other hand, very low humidity may change the shape of some materials, thereby affecting performance. A more serious concern, noted earlier, is that static electricity is more likely to build up in a dry atmosphere. If not actively controlled, humidity tends to drop when air is heated.

The internal temperature of equipment can be significantly higher than that of the room air. Although increasing densities have brought decreasing currents at the integrated-circuit level, dissipation of heat is still a major concern. If a cooling system fails, a vent is blocked, or moving parts create abnormal friction, temperature levels can rise rapidly.

Well below the point at which permanent damage begins (see Table 1), high temperatures can decrease computer performance, sometimes in ways that are not immediately evident; the resources might continue to operate, but with unreliable results. The severity of permanent damage increases with temperature and exposure time. Silicon—the foundation of current integrated circuitry—will lose its semiconductor properties at significantly lower temperatures than what it takes to melt the solder that connects a chip to the rest of the computer.

For perspective, some heat-activated fire-suppression systems are triggered by ambient temperatures (at the sensor) as high as 71°C (160°F). Even in temperate climates, the passenger compartment of a sealed automobile baking in sunlight can reach temperatures in excess of 60°C (140°F). If a mobile computer is directly in sunlight and absorbing radiant energy, the heating is more rapid and pronounced, especially if the encasing material is a dark color, which, in the shade, would help radiate heat.

Although excessive heat is the more common culprit, computing equipment also has a minimum temperature for operation. Frigid temperatures can permanently damage mobile components (e.g., the rechargeable battery of a laptop computer), even (in fact, *especially*) when they are not in use. Plastics can also become more brittle and subject to cracking with little or no impact.

Foreign Substances

Foreign substances—those that do not belong in the information-processing environment—range from insects down to molecules. They can damage equipment and storage media in subtle, perhaps unseen, ways. Often damage results from the combination of a normal motion (e.g., rotation of a disk) and an inappropriate substance.

The most prevalent threat is dust. Even fibers from fabric and paper are abrasive and slightly conductive. Worse are finer, granular dirt particles. Manufacturing by-products, especially metal particles with jagged shapes, are worse yet. Magnetic and optical storage media become a moving part when used in equipment. It is the combination of motion with foreign particles that is particularly damaging. Rotating media can be ground repeatedly by a single particle; a hard-drive head crash is one possible outcome.

A massive influx of foreign particles can overwhelm the air-filtering capability of HVAC systems, which can in

turn result in adverse temperature and/or humidity. The potential causes include the following:

- Controlled implosion of a nearby building
- Catastrophic collapse (such as occurred near the World Trade Center)
- Volcanic eruption
- Dust storm
- Massive wildfire
- Wind storm carrying debris left over from a massive wildfire (as happened weeks after the major fires in California in 2003)

Dust surges that originate within a facility because of construction or maintenance work are not only more likely than nearby catastrophes, they can also be more difficult to deal with because there may be no air filter between the source and the endangered equipment. A common problem occurs when the panels of a suspended ceiling are lifted and particles rain down.

Keyboards are convenient input devices—for dust and worse. The temptation to eat or drink while typing only grows as people increasingly multitask. Food crumbs are stickier and more difficult to remove than ordinary dust. Carbonated drinks are not only sticky, but also far more corrosive than water. In industrial contexts, other hand-borne substances may also enter.

Smoke consists of gases, particulates, and possibly aerosols resulting from combustion (rapid oxidation, usually accompanied by glow or flame) or pyrolysis (heat-induced physicochemical transformation of material, often prior to combustion). The components of smoke, including that from tobacco products, pose all the hazards of dust and may be corrosive as well.

Some airborne particles are liquid droplets, or aerosols. Those produced by industrial processes may be highly corrosive. A more common and particularly pernicious aerosol is grease particles from cooking, perhaps in an employee lunchroom; the resulting residue may be less obvious than dust and may cling more tenaciously.

Water—whether it flows in (from below or above), wafts in (as an aerosol), or condenses (because of high humidity)—is a critical problem in energized electrical equipment. Water's conductive nature (assuming, as is likely, that it is not distilled water) can cause a short circuit (a current that flows outside the intended path). When the improper route cannot handle the current, the result is heat, which will be intense if there is arcing (a luminous discharge from an electric current bridging a gap between objects). This may melt or damage items and may even spawn an electrical fire.

Inappropriate Forces

Although computers and their components have improved considerably in shock resistance, there are still many points of potential failure due to shock. Hard drives and laptop LCD (liquid crystal display) screens remain particularly susceptible.

More insidious are protracted, chronic vibrations. These can occur if fixed equipment must be located near machinery, such as HVAC equipment or a printer.

If sensitive equipment cannot be located away from these sources of vibration, vibration-absorbing mats can be placed under the sensitive equipment or under the offending device. Mobile equipment that is frequently in transit is also at higher risk. Persistent vibrations can loosen things, notably screws, that would not be dislodged by a sharp blow. Even low-grade vibrations will eventually misalign read-write heads.

With the upsurge in mobile computing has come an increased incidence of damage from shock, vibration, dust, water, and extremes of temperature and humidity. One survey found that 18 percent of corporate laptops in “nonrugged” applications had suffered substantial damage (averaging about half the purchase price). Several precautions that should be taken with a laptop are:

- transporting it only in a case designed for that purpose
- making sure it is off (not just in standby mode) when it is stored in its case (to avoid overheating)
- avoiding leaving it where it is subjected to temperature extremes (such as an unoccupied car)
- not subjecting it to moisture, dust, food, or drink
- being careful not drop, bang, or jostle it

Ruggedization of Equipment

An alternative to pampering a device is to make it more resistant to hazards. Laptops and other mobile devices can be “ruggedized” by adding characteristics such as the following:

- having an extra-sturdy metal chassis, possibly encased in rubber
- being shock- and vibration-resistant (with a floating LCD panel or gel-mounted hard drive)
- being rainproof, resistant to high humidity, and tolerant of salt fog
- being dustproof (with an overlay panel for the LCD screen)
- being able to withstand temperature extremes and thermal shock
- being able to operate at high altitude

Touch screens, port replicators, glare-resistant coatings for the LCD screen, and modular components are available on some models. Some portable ruggedized units resemble a suitcase more than a modern laptop.

Ruggedization techniques can also be used for any computer that must remain in areas where explosions or other harsh conditions may be encountered. Accessories available are ruggedized disk drives, mouse covers, transparent keyboard covers, and sealed keyboards (some of which can be rolled up). Some biometric devices can be used in demanding environments.

The term *industrial Ethernet* refers to the use of Ethernet to connect factory floor operations with front-office data systems. Ruggedization aspects associated with this include hardened cable systems, sealed RJ 45 connectors, and M12-4 “D” connectors for tight spaces. Some equipment is designed to operate continuously at 5 to 40°C (41 to 104°F) and 5 to 85 percent humidity and,

for periods up to 72 hours, at even wider temperature and humidity ranges. Seismic racks are specially designed with internal bracing and/or shock absorption to hold servers as well as keyboards and monitors. A commonly applied standard for ruggedization is Bellcore GR-63-CORE.

Physical Access Control for Equipment

It is self-evident that access to equipment must be limited to authorized personnel to prevent vandalism, theft, and inappropriate use.

By comparison with stealing storage media, stealing hardware usually involves removing bigger, more obvious objects, such as computers and peripherals, with the outcome being more apparent to the victim. Garfinkel (2002), however, reports thefts of random access memory (RAM). If not all the RAM is removed from a machine, the loss in performance might not be noticed immediately.

At some facilities, only entrance to areas and/or contact with resources—equipment and storage media—is controlled. When removal of resources (or copies thereof) by persons authorized to have contact with them is a concern, control of egress should be equally important. (See also the comments on the need for and challenges of allowing emergency egress in the later section on “Fire Preparedness.”) There are several philosophical approaches to controlling physical contact with and movement of resources. These methods can be used in combination with one another.

- Physical contact with a resource is restricted by putting it in a locked cabinet, safe, or room; this would deter even vandalism.
- A machine may be accessed, but it is secured (perhaps permanently bolted) to an object difficult to move; this would deter theft. In a variation of this, movement of an object is allowed, but a motion-sensored alarm sounds.
- Contact with a machine is allowed, but a security device controls the power switch.
- A machine can be turned on, but logging on requires a user identification process, possibly involving a password or a biometric device. Related to this is the idea of having the computer “locked” by software (perhaps a password-protected screensaver) while the user is away from the machine.
- A resource is equipped with a tracking device, such as an RFID tag, so that a sensing portal can alert security personnel or trigger an automated barrier to prevent the object from being moved out of its proper security area.
- An object, either a resource or a person, is equipped with a tracking device so that his, her, or its current position can be monitored continually.
- Resources are merely checked in and out by employees, for example by scanning barcodes on items and ID cards, so that administrators know at all times who has what, but not necessarily where they have it.

Specific hardware for controlling physical access is discussed in the major section on facilities because most

devices protect spaces rather than individual pieces of equipment.

Worthy of note here, however, are laptop computers. Because it is often beyond an organization's ability to control access to the space it is in, a laptop provides increased opportunity for theft. According to Gordon et al. (2006), the third costliest category of computer crime for businesses is theft of laptop computers. Rittinghouse and Hancock (2003) suggest that employees sign an acknowledgment of additional precautions to be taken with off-site use of mobile devices. When a laptop must be left unattended, it should be kept in a locked cabinet or car trunk or, at the very least, hidden from the view of passersby. The suggestion to "disguise" a laptop by *not* carrying it in a case designed for it runs contrary to proper practice for protecting the machine from accidental blows, etc. Some hardware devices specific to deterring laptop theft are security cables (for locking the laptop to a less movable object) and alarms.

The prudent assumption is that a laptop will eventually be accessed by an unauthorized person. In addition to hardware and/or software controls for logging in, portable machines should have all stored sensitive data encrypted. There are also software products for helping recover or control stolen laptops. One application has the laptop periodically report its serial number to a central monitoring center. If necessary, the laptop can be traced to its current location. The software is supposed to remain hidden and resident, even if a drive is formatted or the operating system is reinstalled. (See Absolute Software, 2003.)

It is sometimes appropriate for an organization to allow public physical access to some of its computers. In such case, certain cyberprecautions should be taken. Such computers should be on a separate LAN, isolated from sensitive resources. Furthermore, to avoid any liability issues, the public should not be afforded unrestricted access to the Internet.

PHYSICAL SECURITY FOR FACILITIES

Much of the control of physical security for the network resources already discussed—storage media and information-processing equipment—actually takes place at the level of facilities. In particular, control of physical access to spaces, most environmental controls, and most preparations for fire, flood, and damaging forces are done at this level. Each control put in place typically protects multiple pieces of equipment and storage media.

Physical Access Control for Spaces

Controlling physical access to buildings and rooms can be crudely broken down into three aspects: first, barriers and openings; second, lighting and surveillance; and third, detectors and alarms.

Barriers and Openings

The most fundamental protection against intruders is to put obstacles in their way. In doing so, we must not unreasonably impede authorized access or emergency egress. In theory, barriers are preventive measures. In

reality, they are merely deterrents. To paraphrase General George C. Patton, any security device designed by humans can be defeated by humans. Each has its own weaknesses to attacks by stealth or force. The context will determine which type of attack is more likely. Stealthy attacks usually require more expertise and time. Forceful attacks are simpler, but typically are noisier and require larger tools. POA Publishing LLC (2003) has numerous comparisons (some the result of research at Sandia Laboratories) of the time required for and the noise produced by various types of attacks on different kinds of walls, doors, windows, and locks.

The openings required for the passage of people, air, and utilities are the most obvious potential weak points where penetration by people, foreign particles, and fire is easier. In some cases, however, walls have turned out to be easier to breach than locked doors. Doors tend to get the most attention when it comes to protection, but windows, even if sealed shut, are relatively "open" compared to the more impermeable surrounding walls. Some of the unseen openings are easy to overlook, especially below raised floors (common in computing centers) and above suspended ceilings (common in many rooms). These include passages for power and communication lines, water and sewer lines, and ventilation.

The barriers to intrusion form layers, from the campus boundary to buildings to rooms to safes. Using each layer effectively to protect the information-processing environment provides defense in depth.

The outermost barrier can be established at the property line. The sensitivity of a facility may require a wall or fencing. If vehicles must be permitted on the property, the potential for car or truck bombs may require strict control of which vehicles can drive or park where; permanent barriers, pop-up barriers, swing-down arms, "wrong-way" tire-puncturing spikes, and guard houses are possible traffic controls.

The second barrier is buildings. Exterior architecture and landscaping should avoid providing easy access to windows and roofs or obscuring public view of entrances. Regional and seasonal considerations should influence grounds maintenance. In colder climes, security-aware architecture may be nullified if snow is allowed to drift up toward windows or near entrances. In all climates, external construction materials should inhibit ignition by external fires. In dry regions, special care should be taken to keep away from buildings any vegetation with the potential to fuel wildfires. Roofs often have service hatches—for example, to afford servicing of external components of an air-conditioning system. Any roof or windows that might reasonably be accessed via a portable ladder should be protected accordingly.

The third barrier is the surfaces of individual rooms. Floors and ceilings are often forgotten. In the case of a dropped ceiling or a raised floor, the hidden space should not extend above or below multiple rooms if the intention is that access to each room be controlled separately. It is at the level of rooms or groups of rooms that fire divisions (discussed later) are created.

The fourth barrier, within rooms, is vaults, safes, or locked cabinets for storing specific resources. Such containers may serve double duty, providing not only safety

from unauthorized access, but also from certain environmental threats (fire, moisture, electrical fields, magnetic fields, etc.). A safe typically has a combination lock, which may be either mechanical or electrical. The locking mechanism may be a time-delay lock (which cannot be opened until a fixed duration of time after the correct combination has been dialed or pressed) or a time lock (which cannot be opened except during certain predetermined periods). Although these theft-deterrent features are most common when protecting money, they may have wider application as well. Safes are rated by certification agencies (such as Underwriters Laboratories) based on the time it would take for a skilled and suitably equipped safe-cracker to compromise it; the safe, if not monitored remotely, should be visited by a guard patrol at intervals less than the rated time of the safe.

These layers need not restrict access the same way. In some settings, stringent controls at the outermost layer may obviate the need to “recheck” people once they are inside. A more orthodox scheme is to tighten security closer to sensitive resources.

There are a multitude of devices for keeping people out of areas or containers, ranging from padlocks to enclosures with two doors. Fundamental to most systems are the following:

- an immovable barrier (e.g., a wall) with an opening
- a door or comparable part that can be moved to block or to expose the opening
- a way of securing the “door” to the barrier, typically with a bolt or latch

The bolt used to secure a door is usually either a latchbolt or a deadbolt. The former provides greater convenience as it is spring-loaded and beveled, so it slides into the strike when the door is pulled closed. The latter provides greater security, as it requires an additional separate action after the door is closed to move the bolt into the strike. Bolts controlled electrically may be either fail-safe (opening if power fails) or fail-secure (remaining closed if power fails).

Traditional mechanical locks using metal keys are still common and may be adequate in certain situations. They certainly are better than nothing (as is often the case with wiring cabinets). As with encryption, security is no better than key management. Policy guidelines in this connection include the following:

- special security for the key cabinet
- logs of who has which key(s)
- periodic inventories of keys, duplicates, and blanks
- stampings of “Do not duplicate” on keys
- the absence of room or name identification on keys

Comparable precautions must be taken with combinations, personal identification numbers, badges, and cards of various types.

Electronic access control (EAC) systems typically involve a central point of control and monitoring. EAC

systems may provide the security practitioner the following capabilities:

- being able to lock and unlock doors remotely
- being able to log who has entered
- being able to preclude access by specific persons (perhaps everyone)
- knowing when a room is legitimately occupied so intrusion-detection devices can be deactivated (preferably automatically)
- knowing in times of emergency where people still remain

The actual identification mechanism may be the use of some kind of card and/or PIN (personal identification number). The most promising new technology appears to be biometric devices. A major advantage of these is that they depend on a physiological or behavioral characteristic, which cannot be forgotten or lost and which is difficult to forge. There are a wide range of available technologies, which are the subject of the chapter “Biometrics;” consequently, we do not detail the many types of biometric devices in Table 3.

Table 3 lists a selection of the more common components of physical access control systems. Some, such as door closers, must be used in combination with other things.

It is not practical here to enumerate the various techniques for defeating each of the various access control devices listed in Table 3. POA Publishing LLC (2003, 60) lists the average time it takes to surreptitiously neutralize several different kinds of standard locks via different techniques. Whereas most of us probably think of picking a lock or shimming a latchbolt (stereotypically, with a credit card) as the usual attacks on locks, most people do not have the right skills and/or tools for a stealthy attack. Consequently, most attacks are by force. The most vulnerable type of lock is the kind that incorporates the key mechanism in the door knob, common in residential use, as it can easily succumb to an attack by force.

All parts of an opening and its closure are fair game for attacks. Exposed hinges are easy to remove. A strike that is weak or weakly attached will give way under the force of a quickly moving shoulder. The bolt can be exposed by prying a flimsy door jam or “peeling” poorly constructed doors or walls. The locking mechanism itself can succumb to particular types of drilling, punching, hammering, and wrenching.

In assessing a candidate architecture with respect to barriers and openings, the time, resources, and sophistication of a likely hypothetical attacker must be correlated with both the assets it protects (the bigger the prize, the greater the enticement to attack) and the overall security scheme. Of particular note with regard to that overall security scheme is how the choice of openings and barriers should be made in concert with the choice of lighting and surveillance, discussed in the following section. A well-lit, well-observed point of potential attack may not need to be as resistant to the type of attack requiring privacy for an extended time.

Table 3: Physical Access Control Components

Access Control Type	Characteristics
Badge, visitor's pass	Worn by authorized persons, checked by security guards (and perhaps other employees). For employees, should feature a photograph. Features to prevent forgery should be incorporated.
Mechanical key lock	Requires inserting and turning a metal key with a specific configuration. Among various subtypes, pin-tumbler offers better protection than warded, wafer, or lever locks.
Combination lock	Mechanical version involves turning a dial to certain positions. Electronic version requires typing a specific sequence on a keypad.
Card reader	Activated upon insertion of a smartcard or swiping of a card with a magnetic strip or bar code. May also incorporate a keypad for entering a personal identification number. Alternatively, may sense a proximity card without contact.
Hollerith card	Holes in card are read by passage of light or contact brushes. Now used only for hotel security.
Swipe card	Slid through a reader. Can use a magnetic strip or a bar code. Can be used in conjunction with a personal identification number. Magnetic watermarked subtype has magnetic strip embedded, not added on to outside. Infrared shadow subtype is transparent to infrared light, has embedded bar code.
Proximity card	Embedded circuitry emits frequencies that can be detected by a reader when the card is near. Reader can be hidden in a wall. Card can remain inside clothing. Suffers less wear than a swipe card. Same principle can be applied to automobile access.
Memory card	Contains memory circuitry to carry a user's identification information. Intelligent (or protected or segmented) subtype has logic to control memory access.
Smartcard	Contains both memory for a user's identification information and processing power to run related security protocols.
Biometric device	Many subtypes, exploiting physiological and/or behavioral characteristics of the user. (See "Biometrics".)
Stairtower lock	Frame-mounted hybrid electric device. Allows door handle to operate if power fails. Designed for emergency egress.
Magnetic lock	Electromagnet installed on door frame plus strike plate on door. Always a fail-safe device. Direct-hold subtype is surface-mounted on the secure side of door and door frame. Shear (or concealed) subtype is embedded within door and door frame.
Electric strike lock	Solenoid moves a strike from door frame into door. No wiring in door required. Can be fail-safe or fail-secure, use a latch bolt or deadbolt.
Electric lockset	Similar to a mechanical lockset, but with solenoid action in place of key action. Can be fail-safe or fail-secure.
Door closer	Automatically pulls a door shut after it has been opened.
Turnstiles, revolving doors	Used as a choke point (possible with a programmed time delay and sensors in walls) to prevent entry by two people at once ("piggybacking" or "tailgating").
Mantrap (or double-vestibule portal)	Glass enclosure with two doors that cannot be opened simultaneously. Prevents "piggybacking."
Dispensable barriers	Foam, fog, or entangling devices deployed when intrusion is detected. (A "reactive-preventive" measure.)

With regard to the interplay between barriers and surveillance, it is appropriate to single out for comment one particular, common workplace design: a large room with numerous cubicles. The relatively open architecture of cubicles discourages certain types of behavior. On the other hand, the "space" of each cubicle is not lockable as a room is. Removable materials are thus more likely to be

left unattended and insecure during the work day. Even at the end of each day, it is more inconvenient (and perhaps impractical) for a cubicle occupant to secure all sensitive materials. Even if materials are secured, they may be in a type of cabinet offering little resistance to an attack. However, a locked door may give an office occupant a false sense of security; cleaning staff will likely have

access to individual offices. Therefore, at least outside normal working hours, security within an office should be treated as if it were in a cubicle.

Lighting and Surveillance

Whereas barriers can be an obstacle to intrusion, they can also be an aid to it. If, for example, an entrance is sheltered, an intruder has a better chance of picking a lock unobserved. Consequently, one of the principles of crime prevention through environmental design (CPTED) is to increase the perception of natural surveillance—that is, a clear line of sight between the honest and the dishonest. There are several applications of this principle. Outside, fences, doors, and windows should not be obscured by hedges. The architectural design should also present an unobstructed view of doors and windows. Within the workplace, an open design can discourage certain kinds of activities. See Crowe (2004) for a broader discussion of CPTED.

Organized surveillance can be done in person (by stationed or roving guards) or remotely (by camera). In any case, if potential perpetrators are aware of the surveillance, then it can serve as a deterrent, not just as a reactive measure.

Closed-circuit television (CCTV) or digital cameras may or may not be monitored by humans in real time, but some form of recording should be done in any case (to preserve evidence, perhaps for legal proceedings). Recording can be done on analog tape or digitally on hard drives. Real-time monitoring in some form is necessary to interrupt malfeasance before it is completed. For digital cameras, the tedious task of monitoring cameras—perhaps many in number—can be aided by integrating the camera system with motion-detection software or even intelligent software that can recognize suspicious activity or “hot” license plates (of cars known to be stolen or associated with criminals). See [U.K.] Department of Trade and Industry (2005). To the extent possible, care should be taken to install cameras in a way that makes it difficult to disable them or their communication link with a monitor or recorder.

Lighting and surveillance go hand in hand. Whether achieved remotely by cameras or in person, surveillance is aided by lighting. Therefore, good lighting is a deterrent to crime. Although continual illumination is generally preferred, motion-triggered lighting may have more of a deterrent effect in situations in which its activation would be noticed by others more readily than would be the actions of an intruder; an example would be where there are rows of shelving or equipment racks blocking natural surveillance. The most effective type of lighting to support color CCTV cameras is metal halide lamps because they imitate daylight well; however, they are the most expensive type to install and maintain. See Chapter 5 of Cumming (1992) for a comprehensive introduction to CCTV and types of lighting.

Even if surveillance is not a concern, to help prevent accidents, some lighting should remain on outside business hours; it should remain on even if the municipal power supply fails and should not be controllable by any publicly accessible switches. Moreover, additional

lighting triggered by a fire or other emergency should aid escape despite the presence of smoke.

Detectors and Alarms

When prevention and deterrence fail, the next line of defense is to discover, report, and react to fire or unauthorized access. Whether for intrusion or fire, all alarms systems should adhere to the following principles:

- The functioning of detectors and alarms should not depend on the municipal power supply, which can be disrupted; the control unit should indicate the status of both municipal and backup power.
- The remote reporting by detectors should not depend on exposed communication lines that can be cut; alternatives available include radio, microwave, cellular, and satellite communication links.
- Sensing and reporting should be zoned, meaning that responders know an event's location within a facility; ideally, the monitor panel should provide specific information, such as whether a door is still ajar.

A wide variety of devices are available for detecting unwanted intrusions in the form of unauthorized entry or activity. Table 4 outlines the basic characteristics of the main types. Devices should be chosen based on their reliability, features, and cost and on the kind of threat anticipated. The primary consideration, however, is the intended protection pattern. Some devices are strictly for monitoring outdoor areas, perimeters, indoor areas, or items, whereas other types can be used in multiple applications.

Not indicated in Table 4 is the full litany of strengths and weaknesses of the various types of sensors—that is, what causes them to issue false alarms or to ignore suspect events. A very thorough reference for explicit characteristics of sensors is Cumming (1992). Table 11-1 in Fennelly (2004) shows recommendations based on an extensive list of factors affecting sensor usage.

Many sensors have added or optional features (not listed here) that improve their sophistication. It should be noted that the integration—not simply the usage—of two or more technologies can dramatically improve reliability—that is, the likelihood of detecting all and only unwanted intrusions.

Security guards are not listed in Table 3 as an access control device (though they are often used to check badges) or in Table 4 as a detection device (though they often search articles brought in or out). They can be used in both capacities and can also be used to respond to unauthorized entry or behavior. In the present era of hypersensitivity to potential terrorism, behavior is now beginning to be monitored by specially trained security guards for possible indicators of hostile intent. This approach is new and still fraught with false positives (and ensuing indignant reactions by those erroneously suspected), especially in situations (such as in the travel industry) where people may already be under stress.

Guard service is frequently outsourced, a practice that requires depending on the competence and trustworthiness of another organization. Choosing good security guards directly may be a riskier proposition, as determining the reputation of an established security firm is easier

Table 4: Comparison of Types of Intrusion-Detection Sensors

Sensor Type	Characteristics
PIR (passive infrared)	"Sees" change in heat characteristic of human movement. Limited range.
Glass break	"Hears" 3- to 5-kHz sound frequencies and "feels" 200-Hz seismic shock frequencies characteristic of glass breaking; has replaced foil strips previously common on windows.
Acoustic	Microprocessor analyzes shapes of sound frequency to discriminate between breaking glass and other sounds. Best when placed opposite the window to be protected.
Audio	Reacts to and perhaps records the audible range (20–20,000 Hz). Can be attached to a fence to "hear" the sound of it being cut.
Shock	Attached directly to pane of glass. Subtype generating piezoelectric current can protect only one pane. Subtype in which a circuit is "shaken" open can protect nearby panes as well.
Vibration	Reacts to vibrations from forced entry (other than glass breaking).
Electromechanical	Motion breaks or completes an electrical circuit. Largely obsolete. Many subtypes, including pressure mats, metallic foil on windows, door or window switches, and window screens, wooden lattices, or door paneling incorporating fine, easily broken wires.
Ultrasonic	Uses the Doppler effect to detect motion by noting changes in reflections of 19.2-kHz sounds. Limited range. (Can be adjusted to detect air convection from fire, but may be triggered by ventilation system.) Not fooled by movement outside protected room.
Microwave	Similar in principle to an ultrasonic sensor, but using higher-frequency waves, which will penetrate nonmetallic construction. Can be used outside without being inhibited by weather. Can protect perimeters (narrow beam) or areas (wide beam).
Capacitance	Detects changes in capacitive coupling between a ground and an energy-radiating antenna. Very limited range, obsolete except for protecting an individual object.
Photoelectric	Reacts to interference with a beam of light, preferably infrared. Outdoors, weather can interfere with its proper operation.
Chemical	Detects human effluvia. Vapor trace analyzer subtype can test for explosives, inflammables, and drugs.
Balanced pressure	Notes changes in differential pressure in liquid-filled tubes buried under soil. Hard (e.g., frozen) soil may prevent triggering. Nearby traffic may cause false alarms.
Leaky coax	Detects changes in standing pattern of electronic signal emitted by a buried coaxial cable with (partially) stripped shielding. More reliable than balanced pressure sensor.
Fiber-optic cable vibration	Cable can be attached to fences, walls, rooftops, ducts, or pipes or can be buried in ground. Software monitoring changes in signal transmitted through the cable can be "tuned" to ignore certain types of vibrations. Protection extends the entire length of the cable.

than checking the background of each applicant for a security position. Moreover, agencies specializing in physical security provide extensive experience and specialized knowledge, not just expediency. Rittinghouse and Hancock (2003) report that it is "extremely rare" that an outsourcing security company is the problem when there is an internal or external breach of security.

The principle of natural surveillance effectively makes every employee (or, for that matter, helpful nonemployee) a quasi-guard. Those whose primary job function is not security can use a duress alarm to send a signal to a security specialist or law enforcement agency to indicate

that help is needed. This can be of a fixed nature, such as a hidden button a bank teller might use, or can be on a wearable, wireless device. All employees need to know how intruders might enter, how to recognize intruders, and how to react—whom to call and what to do until help arrives. Dealing with intruders is a lengthy subject in itself. A comprehensive list of appropriate actions is given in Chapter 143 of Tyska and Fennelly (2000).

Custodial personnel may need additional training and oversight. They often work at night, a time favored by certain types of intruders. Cleaning crews also are prone to breach security protocols to streamline their work, for

example, by leaving offices open and unattended for periods of time. For this reason, education should be reinforced by spot checks to see what is actually going on.

Environmental Control

As mentioned before, maintaining environmental control may be as critical as maintaining power or telecommunication service. As such, if network equipment is to be kept running despite a loss of municipal power the continuity of HVAC systems' own utilities—power and, if required, water—must be maintained.

HVAC systems should have independently controlled temperature and relative humidity settings. Each variable should be monitored by a system that can issue alerts when problems arise. Ideally, HVAC units should be installed in pairs, with each unit being able to carry the load of the other should it malfunction.

For large, critical facilities, HVAC should be protected from sabotage or "misappropriation" for nefarious ends. In particular, air intakes should be viewed as potential entry points for dangerous airborne substances.

Keeping a computing area free of foreign particles actually requires multiple defenses. Air filters should remove fine dust particles because outdoor dust is brought in on clothes and shoes. Filters must be cleaned or replaced on a regular schedule. Periodically, air-heating equipment should be turned on briefly even when not needed. This is to incrementally burn off dust that would otherwise accumulate and be converted to an appreciable amount of smoke when the equipment is activated for the first time after a long period of disuse. Vacuuming of rooms and equipment should also involve filters. Food, drink, and tobacco products should be banned from the computing area. Maintenance and construction workers (whether they are employees or not) must be made aware of the dangers posed by dust, even from something as simple as accessing the space above a suspended ceiling. When dust-producing activities are anticipated, other employees should know to take precautions, such as installing dust covers on equipment.

Fire Preparedness

Throughout history, fire has been one of the most important threats to human life, property, and activity when measured in terms of frequency, potential magnitude, and rapidity of spread. Fire presents a bundle of the previously mentioned environmental threats. By definition, combustion involves chemical and physical changes in matter, in other words, destruction of what was. Even away from the site of actual combustion, heat can do damage, as detailed earlier. If water is the suppressing agent, it can wreak havoc on adjacent rooms or lower floors that suffered no fire damage. Smoke can damage objects far from the site of combustion, even, in the case of wildfires, after traveling great distances. More critical are smoke's irritant, toxic, asphyxial, and carcinogenic effects on humans; smoke, not heat, is most often the killer in a fire. With the advent of modern synthetic materials, fires can now produce deadlier toxins. Hydrogen cyanide, for instance, is approximately twenty-five times more toxic than carbon

monoxide. Some modern fire suppressants themselves decompose into dangerous substances, as is discussed in the section on "Halon," below. Even the smoke from a single fire has been responsible for chronic illness and cancer in firefighters.

It follows that one of the oldest roles of physical security has been to deal with the threat of fire. There are several sides to this issue: emergency egress, prevention, mitigation, detection, and suppression. Some aspects of fire control pertain specifically to the facilities housing information-processing equipment. Measures that might be adequate in a general setting would be inappropriate for the protection of delicate equipment and media.

A comprehensive tome on fire is Cote (2003).

Emergency Egress

Preservation of human life is the highest priority in fire preparedness. Knowing how to escape from a fire is of the utmost importance because human life has greater value than any information assets. Fire evacuation maps and procedures should be posted and evacuation should be practiced. When the general power supply is cut, signs pointing toward exits must stay illuminated, and some of the lighting along escape routes should also stay on. Ideally, lighting should also come on when a fire has been detected to help evacuees see through smoke.

Fire doors must be latched in fail-safe mode, require only a single action to use, and must incorporate door closers. In particular, emergency exits cannot consist of a sequence of two doors (as in a mantrap, for instance).

Despite good design, instances continue to occur in which well-marked emergency exits have been found to be blocked or locked when the need for them arises. One reason for nullifying a door's panic hardware is that the doors were being used for other reasons, perhaps being propped open, thereby creating the threat of unauthorized entry. If emergency doors are alarmed, misuse of the doors should be rare. If misuse of the doors cannot be prevented by connecting them to alarms, then personnel must be educated as to the threats from misuse. In any case, all employees must know where the emergency exits are, and maintenance personnel must understand the importance of keeping those exits functional.

Governmental regulations may mandate accommodations for persons who have problems with mobility. In the United States, the Americans with Disabilities Act requires that sight-impaired people be able to understand what to do upon touching door hardware, that exit signage meet certain visibility criteria, that exits be usable by weak and wheelchair-bound persons, and that doorways provide at least 32 inches of clearance.

It is possible to install a delayed-egress device on a fire door. The delay can be as long as 15 seconds. A CCTV and remote control of the exit by a guard can be implemented. In such case, the CCTV signal should not be delayed by transmission over low-bandwidth voice communication lines. See Konicek and Little (1997) and National Fire Protection Association (2003, *Life safety code*).

To this point, we have dodged a ticklish issue: The same principles of controlling entrance to areas can be applied to controlling egress—except in times of fire or

other emergency. Allowing quick escape is inherently at odds with checking to see who and what is leaving a building. With an EAC, a person would not be required to use a swipe card to exit; therefore, there would be no record of precisely who exited.

Fire Prevention

In attempting to prevent an accidental fire from ever getting started, the two things best to avoid are high temperatures and low ignition points. It is usually possible to exclude highly flammable materials from the computing environment. Overheating, on the other hand, is a possibility in almost any electrical device and many mechanical devices. In some cases a cooling system has failed or has been handicapped. In other cases, a defective component generates abnormal friction. The biggest threat comes from short circuits; the resulting resistance may create a small electric heater or incite arcing.

Some factors that may lead to a fire, such as short circuits within a machine or a wall, are beyond our control. Yet many precautions can be taken to lessen the chances of a fire. Vents should be kept unobstructed and air filters clean. Power circuits should not be asked to carry loads in excess of their rated capacity. Whenever possible, wires should run below a raised floor rather than on top of it. If wires must lie on a floor where they could be stepped on, a sturdy protective cover must be installed. In any case, wires should be protected from fatiguing or fraying. See National Fire Protection Association (2003, *Standard for the protection of electronic computer/data processing equipment*) for fire prevention guidelines for the computing environment. As of this writing, the newest electrical code pertaining specifically to computing equipment is from the International Electrotechnical Commission (2001).

Many fires are actually the culmination of a protracted process. In some cases, a material smolders for hours before the first flame appears. Therefore, another preventive measure is for employees to use their eyes, ears, noses, and brains. Damage to a power cord can be observed if potential trouble spots are checked. Uncharacteristic noises from a component may be symptomatic of a malfunction. The odor of baking thermoplastic insulation is a sign that things are heating up.

A common, sudden cause of fire is lightning. See the section on "Lightning Precautions," above, for references on lightning-protection systems.

Fire Detection

Automatic fire detectors should be placed on the ceilings of rooms as well as in hidden spaces (e.g., below raised floors and above suspended ceilings). The number and positioning of detectors should take into account the location of critical items, the location of potential ignition sources, and the type of detector. Fire detectors are based on several technologies, outlined in Table 5.

Of the technologies listed, the continuous air-sampling smoke detector is particularly appropriate for computing facilities, as it can detect very low smoke concentrations and report different alarm levels.

For high-hazard areas, there are also automatic devices for detecting the presence of combustible vapors or abnormal operating conditions likely to produce fire. Said another way, they sound an alarm *before* a fire starts.

Some fire detectors, especially the fusible type, are integrated into an automatic fire-suppression system. This means that the first alarm could be the actual release of an extinguishing agent (hence the water-flow detector).

Table 5: Comparison of Types of Fire-Detection Technology

Detector Type	Characteristics
Fixed-temperature	Triggered at a specific temperature. Fusible subtype has metal with a low melting temperature. Quartzoid bulb subtype completes an electrical circuit when a liquid-filled bulb breaks. Line subtype completes an electrical circuit when insulation melts. Bimetallic subtype completes a circuit by bending of bonded metals that expand differently.
Rate-compensation	Triggers at a lower temperature if the temperature rise is faster and at a higher temperature if the temperature rise is slower.
Rate-of-rise	Reacts to a rapid temperature rise, typically 7–8°C (12–15°F) per minute.
Electronic spot type thermal	Uses electronic circuitry to respond to a temperature rise.
Flame	"Sees" radiant energy. Good in high-hazard areas. Infrared subtype may be fooled by sunlight. Ultraviolet subtype may be affected by smoke.
Smoke	Usually detect fires more rapidly than heat detectors. Ionizing subtype uses a small radioactive source (common in residences). Photoelectric subtype detects obscuring or scattering of a light beam. Cloud chamber subtype detects formation of droplets around particles in high-humidity. Continuous air-sampling subtype can detect very low smoke concentrations.
Water flow	Reacts to the activation (or malfunction) of a sprinkler system.

Because an event triggering a fire may also disrupt the electrical supply, fire detectors must be able to function during a power outage. Many fire detectors are powered by small batteries, which should be replaced on a regular schedule. Some components of detectors, such as the radioisotope in an ionizing smoke detector, have a finite life span; the viability of such a detector cannot be determined by pushing the “test” button, which merely verifies the health of the battery. Such detectors must be replaced according to the manufacturer’s schedule.

Fire Mitigation

While fire prevention typically receives more attention in the media, fire mitigation is arguably more important. This is because, despite the best precautions to prevent the accidental ignition of a fire within a facility, a fire may have an external or deliberate origin. Mitigation requires greater planning and expense. The key ideas are to erect fire-resistant barriers and to limit fuel for the fire between the barriers.

For computing environments, the choice of construction materials, design, and techniques for mitigating the spread of fire should exceed the minimum standards dictated by local building codes. Because fires can spread through unseen open spaces, including ventilation systems, a computing area is defined to be all spaces served by the same HVAC (heating, ventilation, and air-conditioning) system as a computing room. Air ducts within that system should have smoke dampers. The computing area must be isolated in a separate fire division. This means the walls must extend from the structural floor to the structural ceiling of the computer area and have a 1-hour rating (resistance to an external fire for 1 hour). Care should be taken to ensure that openings where pipe and cables pass through the fire-resistant boundaries of the separate fire division are sealed with material that is equally fire-resistant.

Many fires affecting a computer area do not actually originate in that area. Even if a fire does not technically spread into a computing area, its products—heat, smoke, and soot (carbon deposits)—may. Consequently, the level of fire protection beyond the computing area is still of critical concern. Fully sprinklered buildings (protected by sprinkler systems throughout) are recommended. Concern should extend beyond the building if it is located in an area with high hazards, such as chemical storage or periodically dry vegetation. In the latter case, an important barrier to fire is a firebreak around the building created by removal of any vegetation likely to fuel a fire.

The standards prescribed by the National Fire Protection Association (2003, *Standard for the protection of electronic computer/data processing equipment*) for fire protection of computing equipment put forth specifications for wall coverings, carpet, and furnishings (which are relaxed in fully sprinklered buildings). Additional prescribed limitations on what other materials can be present in a computer area do not take into account that even high-hazard areas have computers present. In interpreting those standards, one should determine which dangerous materials are absolutely essential for operations, and work to minimize any unnecessary hazards. Because of their potential contribution to fire (as well as being a more likely starting point for a fire), materials that could

contribute to a Class B fire (including solvents, paints, etc.) should not be stored in a computing area except in a fireproof enclosure. Materials that could contribute to a Class A fire (including paper) should be kept to the minimum necessary.

Raised floors are standard features of many computer facilities, allowing for cables to connect equipment without the need to cover cables to prevent fraying and electrical shorting. The use of junction boxes below the floor should be minimized, however. The needed equipment for lifting the heavy removable panels to gain access to the space between the raised floor and the structural floor must be easy to locate, even in the event of a fire.

Fire Suppression

The delicate nature of information resources presents special challenges for firefighting. It is preferable to extinguish a fire with specialized, on-site equipment rather than high-volume fire hoses. Local fire departments should always be informed of any special fire hazards they might encounter on a call. Likewise, they should be made aware of sensitive equipment and media, as well as the fire controls in place. (Newman 2003). Depending on how many operations are automatic, certain employees (enough so that an adequate number are always on duty) must be trained to perform extra duties, including:

- calling emergency officials
- shutting off electricity and natural gas
- altering the air flow (if HVAC is powered from outside the immediate area) so that either smoke is exhausted or it is prevented from spreading inside
- operating special fire systems (hoses, wheeled portable units, manually controlled sprinklers, etc.)

Fire-suppression systems generally release water, dry chemical, or gaseous agents. The release can be from portable devices, from a centralized distribution system of pipes (perhaps with hoses that will be manually directed), or from modular devices in fixed locations. Fire can be extinguished by displacing oxygen, by breaking the chemical reaction, by cooling the fire’s fuel below its point of ignition, or by a combination of these.

Any fire in a computing environment should be considered a Class C fire because of the presence of electricity. Electrical power should be cut as soon as possible, regardless of whether a conductive fire-suppression agent is used, because any electrical shorting will work against the suppressant. Obviously, automatic fire-suppression systems must be able to function independently of the facility’s main power supply.

When possible, it is preferable to extinguish a fire immediately with portable extinguishers aimed at the base of the fire before it can grow. Each device should have one or more letters on the label, indicating the class(es) of fires on which it can be used. For most computing facilities, a dry chemical extinguisher rated A-B-C will cover all situations. The dry chemical will leave a residue, but if the fire can be caught early, this is a small price to pay. All personnel should be acquainted with the location and proper use of portable fire-suppression devices. If more

than one type is available, they must know which type is suitable for which kinds of fires.

Countermeasures must match the potential conflagration, both in quantity and quality. The presence of flammable materials requires greater suppression capacity. In addition, special tools and techniques are needed for special fires. A Class D fire, involving combustible metals such as magnesium, requires the application of a metal-specific dry powder, so named to distinguish its purpose from that of ordinary dry chemical with B-C or A-B-C ratings. (Rechargeable batteries in laptops do not contain enough lithium to require special treatment in case of a fire.) Recently certified, specialized (wet chemical) extinguishing equipment should be installed if there is the potential of a Class K fire, involving cooking equipment using oils and fats at high temperature.

Total Flooding with Gaseous Agents

Total flooding seeks to release enough of a gaseous agent to alter the entire atmosphere of a sealed area (with openings totaling no more than 1 percent of the total surface area of the enclosure). The term *clean agent* is often used to indicate that the gas itself leaves no residue (although its decomposition by-products will). Ordinarily, the air-agent mixture alone would be safe for humans, but fires always produce toxic smoke.

Consequently, the best protocol is to have an alarm continuously announce the impending release of a flooding agent, allow a reasonable time period for personnel to evacuate and seal the area, and sound a second alarm to announce the actual release. Occupants of those areas must understand the different alarms, must know how to proceed when the first alarm sounds, and must appreciate the seriousness of that environment. (A short science lesson might help.) Doors must be self-closing and have “panic hardware” for easy exit. Warning signs must proclaim the special nature of the area. Self-contained breathing equipment must be available for rescuing people.

The sudden release of a highly pressurized gaseous agent has several side effects. The gas undergoes a dramatic decrease in its temperature. Reportedly, skin in direct contact with a release could suffer frostbite. Equipment could suffer as well. The force of the exhaust is considerable and should be taken into account when placing the vents. The noise of a release is loud, but does not impair hearing.

Gaseous fire-suppression systems can be either centralized or decentralized. Centralized systems are generally custom-fitted for a particular installation. A network of pipes delivers the suppressant from a single tank to multiple nozzles operating simultaneously. This is the more traditional and common approach.

Decentralized systems are modular, so there is greater flexibility in placing the individual units or repositioning them (guided by expert advice) if the layout of a facility changes. Independent units each have a tank, triggering device, and nozzle; they can be equipped for remote triggering or monitoring. On the negative side, the individual units, being self-contained, are heavier and bulkier than the outlets and pipes of a centralized system. Therefore, they must be supported from a structural ceiling rather than a suspended ceiling. Moreover, each cylinder

must be anchored very securely to prevent the force of release from turning the cylinder into a projectile subsequent to the release of gas.

Gaseous agents that have been used in total flooding fire-suppression systems in computing facilities include carbon dioxide, argon, nitrogen, halogenated agents (halons), newer replacements for halons, and mixtures of these. (Pure CO₂ at the concentration needed for total flooding is hazardous to humans.)

Halon. For decades, the fire-suppression technique of choice in computing facilities was total flooding with Halon 1301—also known as bromotrifluoromethane or CBrF₃. (Halon 1211, a liquid streaming agent, was also used in portable extinguishers.) Because of their ozone-depleting nature, proportionally worse than chlorofluorocarbons (CFCs), halons were banned by the Montréal Protocol of 1987. Disposal and recycling of Halon 1301 must be performed by experts, because it is contained under high pressure. Consult Halon Recycling Corporation (HRC 2002) for advice and contacts. Although no new halons are being produced, existing systems may remain in place, and the use of recycled Halon 1301 in new systems is still allowed by the protocol (on a case-by-case basis) for “essential” use (not synonymous with “critical” as used by the HRC). Because the world’s supply has been decreasing since 1994, a concern when relying on Halon 1301 is its future availability.

Halon 1301’s effectiveness is legendary. One factor is its high thermal capacity (ability to absorb heat). More important, it also appears to break the chemical chain reaction of combustion. Although the mechanism by which it does this is not perfectly understood (nor, for that matter, is the chemistry of combustion), the dominant theory proposes that the toxins into which it decomposes at about 482°C (900°F) are essential for chemical inhibition. The chemistry and other aspects of halons are discussed in the chapter on Halogenated Agents and Systems in Cote (2003).

In low-hazard environments, a concentration of approximately 5 percent Halon 1301 by volume suffices. Short-term exposure at this level is considered safe but not recommended for humans; dizziness and tingling may result. An even lower concentration is adequate when the Halon 1301 is delivered with a dry chemical that inhibits reignition. Regardless of the concentration applied, immediately after exposure to Halon 1301 (perhaps from an accidental discharge), a victim should not be given adrenaline-like drugs because of possibly increased cardiosensitivity. The real risk comes when fire decomposes Halon 1301 into deadly hydrogen fluoride, hydrogen chloride, and free bromine. Fortunately, these gases, being extremely acrid, are easy to smell at concentrations of just a few parts per million.

Gaseous Alternatives to Halon. In addition to the natural inert gases, there are numerous gaseous replacements for Halon 1301 in the general category of halocarbon agents. Subcategories include: hydrofluorocarbons (HFCs), hydrochlorofluorocarbons (HCFCs), perfluorocarbons (PFCs and FCs), and fluorioicarbons (FICs). None of these or blends of them seem to be as

effective as halons—that is, more of the substance is needed to achieve the same end. The search for better clean agents continues. See National Fire Protection Association (2000, *Standard for clean agent fire extinguishing systems*) for guidelines regarding clean agents and [U.S.] Environmental Protection Agency (2003) for a listing of alternatives.

Water-Based Suppression. Despite its reputation for doing as much damage as fire, water is coming back in favor—more so in Europe than in North America—even for areas with computer equipment. (For areas without such equipment, water is still the preferred, cost-effective response.) Because water's corrosive action (in the absence of other compounds) is slow, computer equipment that has been sprinkled is not necessarily damaged beyond repair. In fact, cleanup from water can be much simpler and more successful than from other agents. Water also has an outstanding thermal capacity.

Misting with water is now used as an alternative to Halon 1301. The decreased droplet size in mists (compared to ordinary sprays) makes them more effective in extracting heat. The explosive expansion of the steam contributes to displacing oxygen at the place where the water is being converted to steam, namely, the fire. (Steam itself has been used as a suppressant.) See, for example, Fleming (1999).

There has also been research with chemically enhanced water mists, but this is not yet in common use.

To reduce the risk of accidental leakage, recommendations have traditionally specified dry pipe systems, in which pipes for hose, sprinkler, or mist systems remain dry until needed. In fact, leakage from wet pipe systems is very rare; damage from washroom incidents is far more likely. See, for instance, Mangan (2002).

Fire Recovery

Even when a fire has been put out, new problems arise—and can intensify as time passes. By-products of the fire, perhaps because of the type of suppressant used, may be toxic to humans or corrosive to equipment. As soon as practical after a fire has been extinguished, thorough ventilation should take place. Only appropriately trained and equipped experts should enter to begin this dangerous procedure. Aside from the initial health hazard, improper procedures may worsen the situation. For example, active HVAC equipment and elevators might spread contamination to additional areas.

Once air quality has returned to a safe level, resources should be rehabilitated. In some cases, equipment will never again be suitable for regular use; however, it may be brought to a condition from which any unique data can be backed up. The same is true of removable storage media. Paper documents can be restored provided they have not become brittle.

The combustion by-products most devastating to electronic equipment are corrosive chloride and sulfur compounds. These reside in particulate residue, regardless of whether dry chemical (which itself leaves a film) or a clean agent (a somewhat misleading term) was applied. In either case, time is of the essence in preventing the

progression of damage. Some types of spray solvents may be used for preliminary cleanup. In the case of fire suppression by water, the procedures outlined below should be followed.

Flood Preparedness

As many have learned too late, much flood damage occurs in areas not considered flood-prone. Flooding, in the broad sense used here, is simply invasive water, whether rising from below, falling from above, or striking laterally. It need not originate in a body of water, and it may be the result of nature or human action. Breaks in water mains can occur at any time, but especially during excavation or winter freeze-thaw cycles. Fire hydrants can be damaged by vehicles. Pipes can leak or commodes overflow. Roofs can be damaged by wind, fallen trees, or snow overburden. Therefore, all facilities should take precautions against flooding from both rising and falling water.

The force of moving water and debris can do structural damage directly or indirectly, by eroding foundations. In some cases, natural gas lines are broken, thus feeding electrical fires started by short-circuiting.

Most flood damage, however, comes from the water's suspended load of particles. Whereas falling water, say from a water sprinkler or a leaking roof, is fairly pure and relatively easy to clean up, floodwater is almost always muddy. Fine particles (clays) cling tenaciously, making cleanup a nightmare. A dangerous biological component may be present if sewage removal or treatment systems back up or overflow or if initially safe water is not drained promptly. Another hazard is chemicals that may have escaped containment far upstream.

When flooding or subsequent fire has disabled HVAC systems in the winter, ice formation has sometimes added further complications. Freezing water wedges items apart. Obviously, recovery is delayed further by the need to first thaw the ice.

Flood Anticipation

Assessing flood risk is no mean task. Government maps depicting flood potential are not necessarily useful in assessing risk because they can quickly become outdated. One reason is construction in areas with no recorded flood history. Another is that urbanization itself changes drainage patterns and reduces natural absorption of water.

Small streams react first and most rapidly to rainfall or snowmelt. Even a very localized rain event can have a profound effect on an unnoticed creek. Perhaps the most dangerous situation is in arid regions, where an intermittent stream may be dry or nearly dry on the surface for much of the year. A year's worth of rain may arrive in an hour. Because such flash floods may come decades apart, the threat may be unrecognized or cost-prohibitive to address.

Usually, advance warning of floods along large rivers is better than for the small rivers that feed them. Because they have a larger watershed, large rivers react more slowly to excessive rain or rapidly melting snow. Formation of ice jams, breaking of ice jams, structural failure of dams, and landslides or avalanches into lakes, however, can cause a sudden, unexpected rise in the level of

a sizable river. People far inland have also been caught by surprise when the less-windy but still-moisture-laden remnant of a hurricane suddenly stalls and quickly inundates a region unaccustomed to or equipped to handle a tropical downpour.

Coastal areas are occasionally subjected to two other types of flooding. The storm surge associated with a hurricane-like storm (in any season) can produce profound and widespread damage, but advance warning is usually good enough to allow for appropriate preparations. Moving at 725 km (450 miles) per hour on the open ocean, tsunamis (seismic sea waves) caused by undersea earthquakes or landslides can be higher than storm surges. Monitors at sea together with computer modeling have aided in posting or canceling some tsunami warnings. However, near-shore events allow little time for warnings. Tsunamis most often strike coastlines on the Pacific Rim since the “Ring of Fire” is responsible for much of the Earth’s strongest seismic activity. However, the largest recorded tsunami occurred in the Indian Ocean on December 26, 2004. An even larger (and rarer) mega-tsunami would affect much of the Atlantic if a particular volcano in the Canary Islands collapses all at once. As the world learned in the 2004 disaster, tsunami warning systems based on ocean buoys are not in place worldwide, and seismic monitoring stations are poorly equipped to alert authorities in all areas in imminent peril. Moreover, some submarine fault lines are so close to land that inhabitants would be inundated within 15 minutes of a quake.

Any urban area is served by an artificial drainage system, the maintenance of which is often at the mercy of a municipality. A violent storm can itself create enough debris to greatly diminish the system’s drainage capacity.

Flood Detection and Mitigation

Water detectors should be placed above and below a raised floor to monitor the rise of water. A sensor that is lower than the lowest energized wire should trigger an automatic power shutdown.

All facilities—but especially those in flood-prone areas—should keep critical resources out of the lowest level or any level below ground level or any known prior flood level. Although safest from rising water, the top floor is the first affected if the roof leaks, collapses, or is blown away. Likewise, the area near a window will be most affected by rain if the window is damaged during a storm.

To mitigate damage from falling water, fitted covers for equipment can, if readily available, be quickly deployed in anticipation of or in immediate response to a damaged roof, overhead pipe leaks, or sprinkler systems. They can also be used as dust covers when equipment is moved or stored, during construction work, or when the panels of a suspended ceiling need to be lifted.

Flood Recovery

The first rule of rehabilitating electrical equipment exposed to water is to disconnect it from its power source. Energizing equipment before it is thoroughly dried may cause shorting, damage, and fire. The second rule is to expedite the drying process to prevent the onset of corrosion. Low ambient humidity speeds drying, whereas

high humidity (and, even more so, dampness) speeds the corrosive action of any contaminants. If the HVAC system cannot (or should not) be used to achieve a relative humidity of 40 to 50 percent, then wet items should be moved to a location where this can be done. Actively applying heat significantly above room temperature must be done with caution. (See the Table 1 for temperatures at which damage can occur to media and equipment.) Handheld dryers can be used on low settings. An alternative is aerosol sprays that have a drying effect. Even room-temperature air moved by fans or compressed air at no more than 3.4 bar (50 psi) can be helpful. In any case, equipment should be opened up as much as possible for the greatest effect. Conversely, equipment should not be sealed, because this may cause condensation to develop inside. Low-lint cotton-tipped swabs may be used to dab water from hard-to-reach areas.

Preparedness for Wind, Seismic, and Explosive Forces

Both wind forces and seismic forces can damage facilities and what lies within them either directly or indirectly—that is, by impelling or toppling a “projectile.” Explosive forces can create both wind forces and seismic forces. Facilities located in regions prone to damaging winds or earthquakes, those that house or are near potentially explosive materials, and those that might invite deliberate acts of sabotage should be “hardened” against such threats. This can be done in a structural sense (preferably at the time of construction) and/or by internal design. In times of impending disaster, additional protective measures can be taken. To the extent practical, all facilities should take similar measures. This is because earthquake-like force and destructive weather can occur anywhere. For example, buildings have collapsed for a wide variety of reasons, ranging from snow accumulation above to water main breaks below; a nearby collapse has a seismic impact on the immediate vicinity. (Even the initial crashes into the World Trade Center registered on seismographs.)

Many regions of the world are subject to seasons when monsoons, hurricanes (typhoons), tornadoes, damaging hail, ice storms, or blizzards are more likely to occur. But global climate change has already resulted in more frequent extreme weather events and more of them occurring outside their customary seasons and regions.

Even if a weather event arrives in its proper season, that arrival may be unexpected. In general, the larger the scale of the weather event, the farther in advance it can be anticipated. Despite dramatic advances in the accuracy and detail of regional forecasting, the granularity of current weather models does not allow precise forecasting of highly localized phenomena beyond saying, “Small bad things may happen within this larger area.” As the probability of any specific point in that area being hit with severe weather is small, such generalized warnings often go unheeded. Even if a warning is noted, there may not be time to “board up the windows.”

Consequently, some standing precautions should be taken regardless of the severe-weather history of a locale. These precautions can serve in case of other disasters

as well. As stated before, fitted covers for equipment can be quickly deployed to protect against falling water from a damaged roof, overhead pipe leaks, or sprinkler systems. They can also be used as dust covers when equipment is moved or stored, during construction work, or when the panels of a suspended ceiling need to be lifted. Keeping critical resources away from windows and off top floors is a good precaution in any location, but particularly in areas where fierce winds could breach the windows, walls, or roofs.

Hurricane-prone jurisdictions are increasingly requiring ever sturdier construction; design consideration should also be given to efficiently protecting windows in advance of an approaching storm. Advanced warning of hurricanes is now adequate to evacuate personnel, crucial media, and perhaps small equipment. In fact, one suite of hurricane-related commercial products can predict peak winds, wind direction, and the arrival time of damaging winds at specific locations.

Facilities in tornado-prone regions should provide for emergency shelter. This involves two things. The first is to construct or at least identify a safe place within the facility, preferably within each building, so people are not required to walk far, especially outside. The other requisite is universal knowledge of where to go. Since tornadoes still, on occasion, arrive with little or no warning, everyone must be ready to move on a moment's notice.

The actual formation of small, intense weather events can be detected by modern radar, and warnings of potential and imminent danger can be obtained through a variety of means. There are radio receivers that respond specifically to warnings transmitted by meteorological agencies or civil authorities. The Internet itself can be the messenger. One mode of notification is e-mail. Other services run in the background on a client machine, checking with a specific site for the latest information. Some of these services are free (though accompanied by advertising banners).

Earthquakes can have widespread effects on infrastructure. The damage to an individual structure may depend more on *where* it was built than on *how*. Buildings on fill dirt are at greater risk because of potential liquefaction, in which the ground behaves like a liquid. Earthquake predictions are currently vague as to time and location.

In regions of the world having a well-known history of frequent earthquakes, planning for the inevitable is second nature. Complacency prevails where damaging earthquakes strike decades or centuries apart; earthquake survivability features may not be required by building codes or may not be calculated to be cost-effective. Fortunately, some cities in seismically dormant areas are waking up to the importance of earthquake precautions.

Regardless of construction techniques, how the occupants furnish buildings is largely their own responsibility. Some precautions can be taken with relatively little expense or intrusion to normal operations. Following are three suggestions from Garfinkel (2002) based on the simple principle that objects will move and perhaps fall from high places to lower places:

- Place computers under sturdy tables, not on high surfaces or near windows.

- Do not place heavy objects so that they could fall onto computers.
- Restrain the possible movement of computers with bolts and other equipment.

The first two recommendations also help in case damaging wind or the force of an external explosion blows out a window or damages a roof. The last could also serve as a theft deterrent, depending on the type of restraint used. There are also relatively easy ways to secure things other than computers. For example, bookcases can be bolted to walls so they cannot topple, and books can be restrained by removable bars or straps. In the newly opened Computer History Museum in Mountain View, CA (10 miles from the infamous San Andreas Fault), some fragile items are bolted down and others are prevented from shaking off shelves by fittings on the front of the shelves (Ward 2004).

Currently, the forecasting of earthquakes is not well focused in space or time. The only certainty is that major shocks are always followed by aftershocks. Therefore, a partially damaged building should not be entered without professional advice on how it is likely to react to an aftershock that could be nearly as strong as the original quake.

Preparedness for Other Disasters

There are a multitude of assorted disasters other than those detailed already. Without attempting to be exhaustive, these include volcanic eruptions, landslides and mudslides, and releases and spills of dangerous substances.

Volcanic ash is one of the most abrasive substances in nature. It can occasionally be carried great distances and in great quantities. If it does not thoroughly clog up HVAC air filters between outside and inside air domains, it may still be tracked in by people. Most volcanic eruptions can now be anticipated with some accuracy, and advanced warning of eruptions has saved lives. Precautions to protect against an influx of ash may be required hundreds of kilometers downwind of an explosive eruption. The Japanese have had some success with constructing structures to divert lava flows, but this is a massive undertaking beyond the means of most organizations. In most areas that might be engulfed by lava, evacuation is the only defense.

Landslides and mudslides may not have the heat (and eventual permanence) of lava, but they can move more rapidly, arrive with less warning, and occur in many more locations than lava. Landslides and mudslides are more common after earthquakes and rainstorms, but they can occur with no obvious triggering event. Often, there is evidence of slow, subtle movement before a collapse. Monitoring of weather, soil conditions, and any changes in potentially threatening slopes may give enough warning to evacuate. Anticipating where slides could occur in the future may require professional geological consultation. As an illustration, a cliff with layers of clay dipping toward the face of the cliff is an accident waiting to happen.

Facilities housing hazardous materials are required to take extra precautions, not the least of which is training

personnel in handling the materials and dealing with mishaps. Every organization should endeavor to determine what hazardous materials are located in nearby enterprises so precautions can be taken as well. Unfortunately, any nearby major transportation route will likely carry a wider array of substances with toxic, corrosive, or explosive potential, and it is impossible to know in advance what might leak or ignite in case of an accident.

Because of the tremendous variety of characteristics of modern contaminants, a facility contaminated by chemical, biological, or radiological agents should not be reentered until local authorities and appropriately trained professionals give clearance. Some contaminants, such as sarin gas, dissipate on their own. Some, such as anthrax spores, require weeks of specialized decontamination. Others, such as radiation, effectively close down an area indefinitely. One helpful action that can be taken during egress or remotely as soon as possible is to shut down air-circulation equipment, as it will tend to distribute airborne particles or molecules.

PHYSICAL SECURITY FOR PERSONNEL

Much of what was said with respect to physical access control for storage media, for information-processing equipment, and for facilities relates to keeping people—insiders and outsiders—from obtaining unauthorized access to information and services. Now we turn to the physical security issues related to personnel (in the broad sense—employees, contractors, and others with “insider” privileges) who have been granted access to information and services to achieve the goals of the organization. As such, they are often referred to as “the weak link.” This usually laments the fact that humans are “human”—that is, fallible. But they can also be a deliberate adversary, potentially the most dangerous of all.

Personnel as Resources

Human beings are the ultimate reason we build networks, and certain humans are employed for the express purpose of keeping those networks running; they are every bit as essential a resource as electrical power and telecommunications service. The protection of humans is mandated by laws, regulations, insurance companies, and basic economics. Even the temporary absence or decreased productivity of individuals soon adds up to a major business expense. For these reasons, employers are increasingly paying attention to environmental hazards and ergonomics in the workplace.

Personnel Availability

The value of human beings was once again evidenced by the fact that response to the New Orleans flood was more influenced by the actions of humans than by planning and equipment. See, for example, Denning (2006) with respect to human behavior in crises.

Although personnel have always been recognized as an essential resource, before the attacks on New York and Washington, the sudden, permanent disappearance of personnel in large numbers was not generally anticipated. Now, business-continuity planners and disaster-recovery

planners, whether focused on preservation of processes or assets, realize that such an occurrence is possible.

Aside from mass slaughter, there are other circumstances in which the availability of human resources may be lacking. Severe weather may preclude employees from getting to work. Labor disputes may result in strikes. These may be beyond the direct control of an organization if the problems are with a vendor from whom equipment has been bought or leased or with a contractor to whom services have been outsourced. A different kind of discontinuity in human expertise can come with a change of vendors or contractors or with the replacement of a large group of workers in one country with workers in another country.

Environmental Hazards

As with storage media and information-processing equipment, humans need reasonable environmental conditions, but humans have their own set of susceptibilities. Employers may be held responsible for a wide range of occupational health and safety issues. Some concerns are common to any indoor workplace. Sick building syndrome may be manifested by a variety of symptoms, including nausea, headaches, dizziness, fatigue, and irritations of the eyes, nose, and throat. The most common cause is poor ventilation combined with indoor air pollution from office supplies and equipment as well as furnishings and construction materials, notably insulation. Minimizing the sources of such pollution may not be as practical as improving ventilation and air filtration, either by means of the HVAC system or stand-alone devices. Another threat is the growth of bacteria or toxic mold from excessive humidity, possibly localized to areas such as washrooms. Eradication of toxic mold can be an expensive, disruptive process. On the other hand, maintaining the proper humidity and ventilation can result in Legionnaire's disease, a form of pneumonia transmitted via mist and sometimes associated with large air conditioning systems; contaminated water in these systems is the suspected source of the *Legionella pneumophila* bacteria.

There is currently no consensus on the long-term effects of extremely low-frequency (ELF) emissions (below 300 Hz)—magnetic fields emitted by a variety of devices, including high-tension lines and cathode ray tube monitors (but not LCD displays). Laboratory tests with animals have found that prolonged exposure to ELF fields may cause cancer or reproductive problems. Studies of pregnant CRT users have produced conflicting data. Pending conclusive evidence, some recommend keeping 60 cm (2 ft) away from such monitors, which may not be practical.

Health worries with regard to cellular phones had mostly been dispelled. But a report of the [U.K.] Health Protection Agency (2005) calls for caution and continued research. Specific concerns are: third-generation (3G) phones, which emit higher levels of radiation; greater sensitivity of children and other groups to radio waves; longer lifetime exposures for those who begin using cellular phones in childhood; and a lack of very long-term data because of the newness of the technology. It has been suggested that children limit use of the devices for voice communication and rely primarily on text-messaging.

Although the World Health Organization acknowledges the need for continued research in certain areas, its latest position is that there is no evidence of health risks associated with exposures to electromagnetic fields below the levels set forth by the International Commission on Non-Ionizing Radiation Protection (1998).

It is known that people with pacemakers should avoid devices creating strong magnetic fields, such as degaussers.

The heat produced by a laptop computer is sufficient that warnings have been issued against using one on bare skin and against falling asleep while having one in a lap. One study done at the State University of New York in Stony Brook indicated that the heat could affect male fertility. (Human Reproduction 2004.)

There is an ever-growing list of potential chemical, biological, and radiological contaminants—each posing its own set of dangers to humans. Most are eventually involved in storage or transportation mishaps. More and more are intentionally used in a destructive fashion. Even if humans are the only component of the computing environment that is threatened, normal operations at a facility must cease until any life- or health-threatening contamination is removed.

Ergonomics

It has been long recognized that the repetitive motions and static positions of workers in many occupations pose health risks. Ergonomically related hazards specific to the computing environment include:

- carpal tunnel syndrome (from repetitive actions, notably typing)
- back and neck pain (from extended use of improper seating)
- eye strain and headaches (from staring at a computer screen for long periods)
- pooling of blood in the legs and increased intraspinal pressure (from sitting for extended periods)

The defense against these is to combine proper equipment, proper relative positioning of equipment and body parts, and proper use of body parts.

Human-friendly appointments pertinent to an information-processing facility include the following:

- a negative-tilt platform for the keyboard and/or mouse
- a specially shaped keyboard or mouse (preferably large and not curved)
- a comfortable, adjustable chair with lumbar support
- appropriately aimed or diffused lighting, a matted working surface, a monitor hood, and/or a screen covering that reduce glare (and, therefore, eyestrain)
- a working surface that can be moved (possibly by means of a motor) to various levels, even to allow use at a standing position
- a movable support to position the monitor
- a document holder, positioned in line with the monitor

Among behavior patterns beneficial to healthy computer usage are:

- sitting at arms' length from the monitor with feet flat on the floor and thighs parallel to the ground
- dynamic sitting—that is, not staying in a fixed position for a long time
- keeping shoulders, arms, hands, and fingers relaxed
- using arm motion (from the elbow) rather than wrist motion to move a mouse
- taking frequent microbreaks, resting on palm supports
- proper relative positioning of chair, monitor, and input devices
- perhaps most importantly, being continually aware of one's own body

Two extensive sources of information on computer workstation ergonomics can be found at the [U.S.] Centers for Disease Control and Prevention (2000) and Cornell Human Factors and Ergonomics Research Group (2004).

Personnel as Threats

Obviously, many of the security threats discussed up until now can be mounted by human beings, and for most of those threats, personnel (employees, contractors, and others with “insider” access) are in a better position to mount the threats (intentionally or accidentally) than are outsiders. The focus now is on two additional areas in which personnel can threaten information and services as outsiders cannot. The first area deals with knowledge that personnel possess as a legitimate part of their job function. The second deals with services to which personnel have access as a legitimate part of their job function.

In numerous surveys, statistics on what percentages of information security incidents and monetary losses are due to insiders and to outsiders vary according to the country, the size, and the performance level (whether “best in class” or not) of the organizations surveyed—not to mention the way in which questions were asked in the various surveys. Moreover, not all studies on information security explicitly distinguish among purely physical attacks, cyberattacks based on physical access, and remote cyberattacks. For a “mid-Atlantic” perspective, compare the surveys by the [U.S.] Computer Security Institute/Federal Bureau of Investigation (Gordon et al. 2006) and the [U.K.] Department of Trade and Industry (PricewaterhouseCoopers 2006), newer editions of which will exist subsequent to this writing. It is generally recognized that insiders are a major (and, by some accounts, the predominant) source of breaches of physical security. While human error is often cited as the leading insider threat, misuse of confidential information and Internet access rank high. Clearly, authorized access to information resources not only increases the opportunity for attacks, but also allows for attacks requiring less sophistication, equipment, and daring.

Mention was made earlier of attempts to gauge malicious intent by observing behavior at checkpoints. Even observing the overall behavior of an insider may be an

exercise in futility. Crume (2000) relates how the characteristics of a model employee may as easily be the characteristics of a corporate spy.

For the threats arising from human failings, the articulation, implementation, and enforcement of a security policy and a thorough security awareness training program are essential. Smaller institutions in which everyone knows everyone else are especially likely to have coworkers who are overly trusting of one another. The corporate culture should foster “collegial paranoia” without breeding mistrust among coworkers. Physical security is just another problem that needs to be attacked with teamwork—a highly valued corporate virtue. That means that everyone should expect cooperation from everyone else in adhering to physical security protocols. For instance, anyone asking to “borrow” someone else’s account should expect to be turned down. Policies must be communicated and justified. Policies that are considered to be frivolous or unnecessarily restrictive tend to be ignored or circumvented. For instance, doors will be propped open when convenience is considered more important than security.

Human-borne Information

Human knowledge is an asset less tangible than data on a disk, but potentially of great value to someone planning to mount a physical attack or a cyberattack. Human-borne information transcends space and time in the sense that personnel can carry potentially compromising knowledge within them to places where there are no corporate laptops or disks, and they may maintain that knowledge beyond their employment at (or even the existence of) an organization.

Human-borne information can be roughly lumped into two categories. Primary information is the lifeblood of the organization, the information that is the main security objective. Secondary information is that which relates to securing the primary information.

Primary information may include customer information, confidentiality of which may be mandated by government legislation and regulation, such as, in the United States, for example, the Sarbanes-Oxley (SOX) Act, the Gramm-Leach-Bliley Act, the Health Insurance Portability and Accountability Act (HIPAA), and California Senate Bill 1386 (which governs persons or businesses that conduct business in California). Primary information may include product development and marketing plans, revelation of which might forfeit a competitive advantage. It may also include trade secrets.

Secondary information may include passwords, but also information about how an internal network is configured, whether there are hidden cameras, when security guards make rounds, etc. Although not the focus of the security effort, a compromise of the secondary information could clearly lead to a compromise of the primary information.

The threat of human-borne information’s falling into the wrong hands can come in several forms. An employee may directly leak information by their willful or inadvertent action or inaction. Or he or she may be duped or coerced by someone (not necessarily an outsider) into yielding information or access to services. In still other

cases, it may be possible to glean from public sources information that may aid an attack.

Passwords

Some of the best-known breaches of security involve network-access passwords. A password written down on paper invites a crime of opportunity to anyone who finds the paper. The same effect can be achieved by “shoulder surfing” even if the password is not written down. Employee voice mail, even personal voice mail at home, has been compromised for the purpose of obtaining sensitive information such as reset passwords. A password that is predictable based on the life of the associated employee (birth date, spouse’s name, etc.) does not require physical access to a piece of paper, but rather personal acquaintance with the employee. Of course, if a computer has been left unattended while logged on, or if one employee willingly “shares” an account with someone else, no password is needed for an attacker to establish a foothold.

The defense is the establishment and enforcement of policies mandating strong passwords, banning the writing down of passwords, requiring “locking” a computer (by reverting to the password-protected log-in screen) when unattended, and prohibiting the sharing of an individual account or the assigning of a common account name and password to a group of people (because this complicates tracing malfeasance to a single person). This highlights the challenges of what is often called personnel security. Automatic, iron-clad cyberenforcement of policies dictating the length, composition, or life span of passwords is trivial. On the other hand, enforcing a policy such as, “Eat it if you write it down,” is essentially impossible to enforce. At the same time, stringent password policies commonly result in passwords that are hard to remember and short-lived, thereby provoking users to write them down.

Social Engineering. A deliberate way of gaining unauthorized access to resources is social engineering, the art of conning others into acting on one’s behalf to achieve one’s own, illegitimate end. The victim usually realizes the information is privileged, but the perpetrator—who may or may not be an outsider—successfully impersonates an insider having some privileges (“I forgot my password ...”). The request may be for privileged information (“Please remind me of my password...”) or for an action requiring greater privileges (“Please reset my password...”). Of course, the information or action sought need not involve passwords.

Larger organizations are more easily victimized by social engineering because no one knows everyone in the firm. Social engineering can be done in person, over the phone, or via the Internet.

The defense is to institute social engineering awareness training that provides sample scenarios. Some interesting examples of engineering attacks both by phone and by e-mail can be found in the penetration testing checklist of Orrey and Lawson (2006).

See also “Social Engineering” for a thorough treatment of this area.

Information Mining. Less famous than social engineering are methods of mining public information posted by

personnel, either in an official or an unofficial capacity. Some information must necessarily remain public, some should not be revealed, and some should be obfuscated.

Domain name service information related to an organization—domain names, IP (Internet protocol) addresses, and contact information for key information technology (IT) personnel—must be stored in an online “whois” database. If the name of a server is imprudently chosen, it may reveal the machine’s maker, software, or role. Such information makes the IP addresses more useful for cyberattacks. Knowing the key IT personnel may make it easier to pose as an insider for social engineering purposes.

Currently, the most obvious place to look for public information is an organization’s own Web site. Unless access is controlled so that only specific users can view specific pages, anyone might learn about corporate hardware, software, vendors, and clients. The organizational chart and other, subtler clues about corporate culture may also aid a social engineering attack. Of course, this information and more may be available in print.

Another dimension of the Internet in which one can snoop is newsgroup bulletin boards. By passively searching these public discussions (“lurking”), an attacker might infer which company is running which software on which hardware. He or she may instead fish actively for information. An even more active approach is to provide disinformation, leading someone to incorrectly configure a system.

All employees who know anything that might be useful to a potential attacker should be given awareness training with regard to indiscreet usage of newsgroup bulletin boards, etc. As with social engineering, sample scenarios should be described.

Appropriate Use. An increasingly nagging and complex issue is the personal use of network resources by those who are authorized to use the resources as an essential part of their work-related duties. It is typically done without malice or any thought that it has any significant adverse impact on the organization. Current attitudes toward intellectual property rights are a major societal problem. A pilferer of “excess” computing power may view his or her actions as a “victimless crime.”

Before the digital age, infractions would have been on the level of personal phone calls and photocopying. Now there are far more ways to misappropriate resources, and inappropriate use of network resources has far more legal and ethical implications than older forms of misbehavior. Acts of misappropriation by personnel may compromise confidentiality, authentication, and authorization and may even have impact on availability and integrity.

Currently, one of the most pressing problems is how employees abuse Internet access in the workplace. Volonino and Robinson (2004) cite two studies that quantify the magnitude of the problem. One, by IDC Research, estimates that 30 to 40 percent of workplace Internet usage in 2003 was not work-related. In another, Websense claims that cyberslacking costs U.S. businesses \$85 billion per year in lost productivity. It should come as no surprise, then, that surveys of U.S. companies indicate the proportion monitoring employees’ Internet activities is about 63 percent, 80 percent for larger companies.

Forms of inappropriate use of network resources include:

- accessing confidential data for personal reasons
- downloading pirated music or software
- launching cyberattacks or enabling resources to become launching points for attacks by others
- downloading child pornography
- creating a hostile work environment because of downloaded materials
- exchanging information in connection with criminal activities—for example, fraud or money-laundering

The consequences of these inappropriate uses include:

- lost productivity due to time misspent
- expended bandwidth and, therefore, reduced speed for appropriate, work-related activities
- legal action based on employee claims of a hostile work environment
- legal action based on violation of intellectual property rights
- legal action based on the use of resources (even if by outsiders) in illegal activities
- damage to an organization’s reputation

Beyond the obvious waste of time for which employees are being compensated, there may also be a significant impact on an organization’s available bandwidth. In academic institutions with lax controls over student usage, the (often illegal) downloading of entertainment media has, in some cases, exceeded the volume of all other Internet traffic. From a practical standpoint, inbound or outbound Internet traffic can be selectively blocked, filtered, or shaped; the last is the least intrusive because it limits the portion of bandwidth that can be consumed by certain services while not prohibiting them entirely.

The direct impact on the bottom line is not the only consequence of improper use. Legal precedent has established that a company that does not actively prevent inappropriate behavior by its employees within the job’s time-space domain is seen as promoting that misconduct and may be held liable for it; this is the principle of respondeat superior. Violation of intellectual property rights is one concern. When the Internet activity of some employees offends other employees, a company is likely to incur legal action for neglecting its duty of care obligations to employees by allowing the creation of a hostile work environment.

PHYSICAL SECURITY FOR TRANSMISSION MEDIA

Of the various resources critical to network communication, the resource most far-flung and arguably hardest to secure is transmission media. It is often largely beyond the control of an individual organization.

The availability of telecommunication service was dealt with earlier. The remaining issue is controlling physical access to transmission media at and between

standard access points. Unguided transmission media such as microwave (whether terrestrial or satellite), radio (the easiest to intercept), and infrared (the hardest to intercept) should be considered fair game for outsiders to intercept at the air interface. Because of their inherent vulnerability to eavesdropping, wireless digital transmissions should be encrypted (a cyberdefense) and analog voice communication should be scrambled if confidentiality, integrity, or authentication is desired. Therefore, interception between standard access points will be considered only for guided transmission media.

Standard Access Points

Connecting to a network, whether copper-based or fiber optic, is easiest at (unguarded) standard points of access. Examples are: a live, unused local area network (LAN) wall jack; a live, unused hub port; and a LAN-connected computer that no longer has a regular user. For the perpetrator, these approaches involve varying degrees of difficulty and risk. The second approach may be particularly easy, safe, and reliable if the hub is in an unsecured closet, the connection is used for sniffing only, and no one has the patience to check the haystack for one interloping needle. Defenses are to secure wiring cabinets and to establish and enforce policies that remove or nullify access points as soon as they are not needed; computers that are no longer needed on the LAN should be locked away and have their hard drives sanitized.

A slightly different issue is employees' installing unauthorized modems, sometimes to facilitate work-related activities either at home or, in some cases, at the office (Skoudis 2000). These can provide entrée to an outsider who would otherwise be stopped by a corporate firewall. Even IT administrators, who should know better, leave "back-door" modems in place, sometimes with trivial or no password protection. Checking for rogue modems can be done either by visually inspecting every computer or by "war-dialing" all possible company extensions.

A related issue is the risk posed by broadband access by home users; depending on how the laptop's access to the Internet and access to corporate information are controlled, a compromising of a laptop while used at home by an employee may lead to the compromising of corporate information.

Although more related to cybersecurity, it is worth noting in passing that a computer user may transform the nature of a standard access point by installing software (e.g., Skype) that uses a "rogue" VoIP protocol, which establishes a direct connection with other computers. Reconnex (2006) discusses the dangers of and solutions to this type of access.

As mentioned above, a particularly easy attack is to use a computer to which an authorized user has already logged on or to which one has been able to learn the password. One way to learn a password or any other information typed on keyboard is with a keyboard monitor, a small device interposed between a computer and its keyboard that records all keystrokes. The attacker (or suspicious employer) must physically install the item and access it to retrieve stored data. (Hence, keyboard logging is more often accomplished by software.)

Wiretapping Guided Transmission Media

Aside from outright damage to guided transmission media, typically via a construction misadventure, the primary security concern associated with guided transmission media is wiretapping. The term originally referred to making a surreptitious (perhaps legal) connection with telephone lines, often with a transmitting device. See the chapter "Voice Communication Systems." We simply point out that more sophisticated equipment (e.g., a nonlinear junction detector or a telephone analyzer) is generally expensive. See Purpura (2002). In the more general sense intended here, *wiretapping* refers to making physical contact with transmission media at points other than standard access points for the purposes of intercepting information.

Copper-wired media are relatively easy to tap. Visual inspection of all exposed wires may be difficult. A more practical reactive measure is to detect a tap using time-domain reflectometry (sending a pulse down the wire and analyzing the signal that bounces back) together with a baseline reading of cable in an "involute" state. A preventive measure is to enclose in pipes all cables that are not in secured spaces; the pipes should themselves be protected against tampering.

According to Oyster Optics (2003), "Although it was initially thought that these optical fibre systems would be inherently secure, it has been discovered that the extraction of information from optical fibers is relatively simple and is aided by the increasing sophistication and availability of standard test and maintenance equipment." This can be accomplished by bleeding off less than 1 percent of the light, an amount less than normal operational variations. There are two ways to do this. Macro-bending involves flexing the cable in the way a road would curve, then suitably aligning an optical detector. Micro-bending consists of creating ripples in the surface of an otherwise straight (and perhaps fully coated) cable by clamping onto it a device with ridges; the optical detector is incorporated into the clamp.

One defense against this is to use optical time-domain reflectometry, which is analogous to the electronic version mentioned above. However, this may not be able to detect the small loss of light required to obtain meaningful information from a line. An alternative is a relatively new technique to detect physical disturbances in the cable that do not even involve a loss of light. (The same principle can be used to protect a variety of items, even very large ones, by attaching a nondata fiber-optic cable; see the last line in Table 4.) This form of defense is described by Future Fibre Technologies™ (2005).

Incidental Compromising Emissions

As mentioned with respect to EMI, all electrical devices and wires emit electromagnetic radiation. Even electronic equipment *not* designed to broadcast information may produce unintended emanations containing recoverable information. Unshielded twisted-pair cabling emits most readily. Fiber-optic cable stands alone for its inability to radiate or induce any signal detectable without contact. Mobile detectors have been used to locate radios and televisions (where licensing is required) or to determine

the stations to which they are tuned. Video displays (including those of laptops) are notorious emitters; inexpensive equipment can easily capture scan lines, even from the video cable to an inactive screen.

Electronic emissions are considered “compromising” if they contain sensitive recoverable information. The term *tempest* originated as the codename for a U.S. government program to prevent compromising emissions. (Governments are highly secretive in this area; contractors need security clearance to learn the specifications for equipment to be tempest-certified.) Related compromising phenomena are as follows:

- hijack—signals conducted through wires (and perhaps the ground, as was noted during World War I)
- teapot—emissions intentionally caused by an adversary (possibly by implanted software)
- nonstop—emissions accidentally induced by nearby radio-frequency (RF) sources

One attack is to irradiate a target to provoke resonant emissions—in other words, intentional nonstop. (This is analogous to how an infrared beam can expropriate acoustic information.) Interestingly, equipment certified against passive tempest eavesdropping is not necessarily immune to this more active attack. Although these emissions were formerly the concern only of governments, increasingly less expensive and more sophisticated equipment is making corporate espionage a growing temptation and concern. An excellent introduction to this area is Chapter 15 of Anderson (2001). A well-known portal for tempest information is McNamara (2002).

PHYSICAL SECURITY PLANNING

Physical security planning involves gathering information about the assets to be protected and potential threats to them, determining and implementing appropriate preventive practices, and planning for recovery if a disaster nevertheless occurs.

Physical Asset Identification

The first and most obvious question to pose during security planning is: What are the assets to be guarded? Physical security seeks to protect the five major networking components featured in Figure 1: storage media, information-processing equipment, facilities, personnel, and transmission media. It will be appreciated that an attack on any of these that results in a breach of the confidentiality, integrity, availability, or usage authorization of information or services associated with an organization may also be an attack on other, less tangible assets, such as an organization’s reputation, which in turn may ultimately be an attack on the organization’s bottom line and survival. Thus, a starting point may be to think backward, from the mission of the organization to the role networking resources play in achieving that mission.

Formerly, to answer the question of what assets needed to be guarded, one relied entirely on a manual inventory. Now there are asset management tools that can track the location and migration of hardware and software. These

can manage software licenses and monitor security policy violations, such as unauthorized software or outdated virus definitions. See, for example, Absolute Software (2003).

The natural follow-up or concurrent question is: Where are the assets located? Clearly, the location of any asset influences which defenses can be put in place. For example, the options for guarding a laptop are different than for guarding a server. More important is how the location of an asset influences the risks associated with it and therefore the defenses that should be used.

Physical Threat Assessment

Having determined what is to be protected, the logical question to answer is: What is likely to go wrong in the future? Unfortunately, it is human nature to dwell on answering a simpler question: What has gone wrong in the past? Since looking back in time is infinitely easier than looking forward, the temptation is to “fight the last war,” a trap that has snared many a general; a reminder is the sequence of low-tech forms of attack mounted by Iraqis seeking to expel high-tech invaders. An understanding of past glitches and disasters is essential, but not sufficient. Not all that *will* happen (in your neighborhood or in the world) *has* happened. Many events are common enough that we can reasonably trust probability tables constructed for them. Others calamities have yet to be invented. To expand George Santayana’s famous quote, those who are ignorant of history are doomed to repeat it, but those who live in the past are also doomed.

The apocalypse in New Orleans is a reminder of another saying: “None are so blind as those who will not see.” Despite decades of dire predictions and days of forewarning, officials at all levels stared at an oncoming Category 5 Hurricane Katrina (which was only at Category 3 strength when its weaker side hit New Orleans) and refused to see that *everyone*, even those without cars, needed to be evacuated *before* the storm arrived.

Similarly, there are large institutions that, despite abundant experience with blizzards, blackouts, and other calamities of regional scale, blindly insist on having their backup facilities in the same metropolitan area as their primary facilities.

The key to preventing physical breaches of confidentiality, integrity, and availability of network resources is to anticipate as many bad scenarios as possible. A common flaw is to overlook plausible combinations of concurrent problems, such as the incursion of water at the same time backup power is needed. Another error is to become frozen in time, forgetting that, to cite another cliché, nothing is constant except change. Periodically, the threat space (and, therefore, the assets) must be reassessed.

Physical Security Practice

Having determined the physical assets to be protected and the threats to those assets, physical security can be put into practice by identifying appropriate countermeasures and then establishing and implementing a preventive physical security policy for personnel. Periodically, the effectiveness of the countermeasures chosen and the actual

implementation of the established policies by personnel must be tested. Terms such as *computer security audit* and *penetration testing* have come to be applied more to cybersecurity than to physical security, but the same general principles apply to each. *Auditing* is a more general term that can include interviews of personnel, analysis of systems, review of logged incidents, and testing. Black box, white box, and various levels of gray box testing are performed with no, complete, and partial information, respectively, of the security system in place. Audits and testing can be performed by regulatory agencies, specialized security companies, or internal staff.

Physical Security Measure Identification

Determining the appropriate physical security precautions to take begins with the information obtained in the physical security audit, knowledge of the defensive countermeasures presented above and in other chapters, and a large dose of pragmatism. The past has taught us that preventing *all* bad events is impossible, regardless of the time, effort, and money invested in preventive measures. There *will* be failures. For integrity and availability of resources, redundancy can be used as a remedy when the worst-case scenario becomes reality, allowing one to “go back in time” to some extent. Unfortunately, there is no comparable way to undo a breach of confidentiality.

The inherent intractability of physical security requires one to approach it in a pragmatic and fiscally responsible way. This cannot be done without answering another question: What are the guarded assets worth? It may be natural to ask this question when the assets are identified, but it is mentioned here because the answer may depend on the particular threat to an asset. It is simplistic to say that the cost of protecting an asset should not exceed the value of the asset. It is more precise to say that the cost of protecting an asset against a particular type of attack should not exceed the liability if the attack succeeds. That liability may be many orders of magnitude greater than the cost of the asset. The marginal cost of creating a customer's bank account may be relatively small. The impact could be huge if an unauthorized person were to drain the account or if sensitive financial information were revealed to the public. An organization failing to exercise due diligence may be subject to lawsuits, fines, and/or other legal sanctions. Even the financial losses directly related to a failure to maintain physical security may be small compared to the later consequences of a widespread loss of clients' confidence in an organization. Admittedly, an estimation of an asset's value may be fairly unreliable, especially for a less tangible asset. But measuring a potential loss in monetary terms helps justify an investment in security measures.

As a practical matter, the probability of each type of potential breach of physical security must also be factored in when comparing the potential liability incurred by the breach and the expense of preventing that particular event. This allows one to compute the (probabilistically) expected benefit of adopting a security measure. As mentioned above, the probabilities of some events will be more difficult to estimate than others. According to Gordon (2006), most organizations use either return on

investment (ROI), internal rate of return (IRR), or net present value (NPV) to evaluate the cost-effectiveness of security expenditures.

Physical Security Policy for Personnel

Physical security measures comprise two disparate components—suitable objects (perhaps incorporating software) and suitable practices by personnel. Action items in a physical security plan may be discrete events that support physical security measures, such as the installation of a lock on a door or the instatement of a policy that the door should be locked. On the other hand, there is the continual vigilance needed to consistently abide by the policy and use the lock. A classical view is that corporate respect for the importance of security must start at the top of the organization and be communicated downward through the chain of command.

At its inception, a physical security policy is established and articulated through employee education. Thereafter, it must be implemented and enforced. Periodically, the policy must be reviewed and revised, with concomitant reeducation.

A particularly tricky issue is establishment of an acceptable-use policy that strikes the right balance. Some employers prohibit even personal e-mail to an employee's spouse saying, “I have to work late”—a practice this spouse has found to be both ironic and very inconvenient. Others seem not to care about misuse of resources until glaring abuses arise. Neither policy extreme is optimal; research has shown that productivity is actually best when employees are allowed modest time for personal e-mail and Internet access. To install a favorite snapshot on an employee's computer desktop screen is considered a *de facto* right as much as to place a family photo on his/her desk. A thorough introduction to the subject is contained in Chapter 6 (Acceptable-Use Policies) of Volonino and Robinson (2004).

Depending on the jurisdiction and circumstances, companies may be required to announce monitoring of employees' usage of their resources. For example, under the U.K. Data Protection Act of 1998, covert monitoring is allowed only if there are clear grounds for suspecting criminal activity. If activity monitoring is used, the notification of employees (whether legally required or not) may create some animosity, but much less so than when it is eventually discovered that secret monitoring has been in effect. It is best to spell out both what an employer expects in the way of behavior and what employees might expect with regard to what they may see as their “privacy.” In practice, monitoring should be used to control problems before they get out of hand, not to ambush employees.

Corporations have taken a number of approaches to enhance security awareness, including the following:

- publishing policies in handbooks, memos, etc.
- requiring courses (perhaps self-study) before activating user accounts
- periodically testing employees for knowledge of policies

For physical security, implementation and enforcement of a policy is far more difficult than establishing the policy and training personnel.

Checking on employees' computer usage is easy. Best practices on choosing passwords can be rigidly enforced. Storage areas on workstations and on servers can be checked to see that all stored content is work-related. In addition to monitoring e-mail passing through their hardware, companies use activity monitors, software to record keystrokes, to capture screen displays, or log time spent on Internet chatting, game playing, etc. Some activity monitors can be set up to alert administrators to inappropriate behavior or to block use of certain applications or Web sites. Some products claim they cannot be detected, located, deactivated, or removed, even by experienced users. Other products exist to detect or even block any key-logging software.

The problem is that computer usage monitoring as described actually covers a small fraction of the spectrum of security-related behavior. So much of physical security is *not* about keystrokes and mouse clicks. It is about not writing down passwords, not talking to strangers, not propping doors open, etc.

Chapter 8 of Wylder (2004) discusses the various past approaches to enforcement and the problems each has encountered. He advocates and details a bottom-up approach that emphasizes personal accountability; in a nutshell, a personal security plan is created and incorporated into employee performance assessments. This approach makes security more analogous to occupational health and safety, for which employers and employees share responsibility for maintaining an appropriate work environment.

Ultimately, the employees' competence and trustworthiness are invaluable defenses. The former is much easier to ensure than the latter. Managers at all levels must appreciate the potential for attacks from within, understand the various motivations for such attacks, and guard against provoking negative attitudes toward the organization either by how they treat subordinates or by how they themselves behave in the workplace.

It goes without saying that once his or her employment with an organization has ceased, an ex-employee is not under the same type of control by his or her former employer. But while admonitions and disciplinary actions (even the threat of a pink slip) might no longer be available to the ex-employer as options for applying security-compliance leverage, the organization may still have legal recourse (and, therefore, a measure of leverage)—provided restrictive covenants were included in the employment contract. See, for example, Ogilvy Renault (2006) for general guidelines for increasing the likelihood that a restrictive covenant will be legally enforceable.

Along the same lines, "insiders" who are not employees—contractors, vendors, clients, corporate partners, and the like—are inherently more detached from an organization's control than is a full-fledged employee. Again, the organization must proactively use legal means to protect any of its intellectual property that must be revealed to said insiders. A nondisclosure agreement (NDA) between the organization on the one hand and the insider and/or the insider's employer on the other hand must be signed before the transfer to the insider of any confidential materials or information to be covered by the NDA. NDAs should be drawn up by legal counsel cognizant of

what intellectual property should be covered, who must sign, and what legal remedy may apply if the terms of the agreement are broken. Even when an NDA is in place, confidential information should be shared only on a need-to-know basis (a basic security principle that should apply even within an organization).

Disaster Recovery Planning

Disaster is in the eye of the beholder. If it is *your* hard drive that crashes while holding unique data, it is a disaster. Other events, such as the destruction of an entire building, may be far more disastrous in one sense; yet, with the proper planning, an organization might continue to function with no loss of data or services.

Disaster recovery can take as many forms as the disasters themselves. A single event may be handled in different ways or may require a combination of remedies. Data and services replicated elsewhere may be called into service. Media and equipment may be rehabilitated on- or off-site. Simultaneously, operations may be (partially) restored on-site or transferred off-site. In most disaster recovery planning, the first priority is maintaining operations or restoring them as soon as possible. There are a variety of services that can be contracted to resume operations or to rehabilitate damaged media, equipment, and buildings. Some are mobile facilities. See the chapter "Business Continuity Planning."

We concentrate here on the physical aspects of rehabilitating buildings, equipment, and media. Professional disaster-recovery services should always be used for this purpose. Because such specialized companies are not based in every city, however, their response time does not match that of emergency personnel. Yet for many physical disasters, the first 24 hours are the most important in limiting progressive damage, for example, from water and smoke. Consequently, knowledge of what to do during that crucial time is essential. Good references in this regard are McDaniel (2001) and the three separate links on "What to do in the first 24 hours!" (for electronics; for magnetic, optical, information media; and for documents and vital records) at the press releases Website of BMS Catastrophe (2002).

CONCLUSION

The scope of physical security is wider than is immediately evident. It concerns an organization's resources, wherever they go. An asset often forgotten is employees' knowledge. Equally important are their intentions. Thus, any employee has the potential to pose or mitigate a physical threat.

In the realm of security for computer networks, physical security tends to receive less attention than cybersecurity. Yet the two sides of security must work together to defeat malicious insiders and outsiders. Ultimately, physical security is the greater challenge, because nature can be the biggest foe, and insiders with authorized access are the most prevalent threat.

Physical security has grown from its simple, ancient roots into a modern, highly complex field involving

a broad range of topics outside the normal sphere of IT expertise. Consequently, to obtain the best protection, professionals in other fields should be consulted with regard to HVAC, fire detection and suppression, power maintenance and conditioning, physical access control, forensic science, managerial science, and disaster recovery. A basic understanding of how these areas relate to physical security facilitates communication with consultants. Combining knowledge with the imagination to expect the unexpected leads to better physical security planning and practice.

GLOSSARY

Bolt: A bar that slides into a *strike* to attach a movable object (e.g., a door) to an immovable object (e.g., a door frame).

Class A Fire: Fire involving ordinary *combustibles* (e.g., wood, paper, and some plastics).

Class B Fire: Fire involving *flammable* or *combustible* liquid or gas (e.g., most solvents).

Class C Fire: *Class A* or *Class B* fire amid energized electrical wiring or equipment, which precludes the use of extinguishing agents of a conductive nature (e.g., water or foam).

Clean Agent: Gaseous fire suppressant that technically leaves no residue; residues will result when the agent breaks down under the heat of combustion.

Combustible: Capable of burning at normal ambient temperature (perhaps without a flame).

Degausser or Bulk Eraser: Alternating current-powered device for removing magnetism. (*Degausser* is often applied specifically to wands that rid cathode-ray-tube monitors of problems displaying colors. The term *bulk eraser* indicates that data are wiped en masse rather than sequentially.)

Electrical Noise: Electromagnetic interference, especially interference conducted through the power input, or minor *spikes*.

Electromagnetic Interference (EMI): Undesired electrical anomalies (imperfections in the desired waveform) due to externally originating electromagnetic energy, either conducted or radiated.

Flammable: Capable of burning with a flame; for liquids, having a flash point below 38°C (100°F).

Halon or Halogenated Agent: *Clean agent* formed when one or more atoms of the halogen series (including bromine and fluorine) replace hydrogen atoms in a hydrocarbon (e.g., methane).

Heating Ventilation Air Conditioning (HVAC): Equipment for maintaining environmental air characteristics suitable for humans and equipment.

Line Filter: Device for “conditioning” a primary power source (i.e., removing *electrical noise*).

Nondisclosure Agreement (NDA): Legal contract governing the use and disclosure of one party’s confidential information by another party.

Radio-Frequency Interference (RFI): Sometimes used as a synonym for *EMI*, but technically the subset of *EMI* due to energy in the “radio” range (which includes frequencies also classified as microwave energy).

Sag or Brownout: Drop in voltage.

Smoke: Gaseous, particulate, and aerosol by-products of (imperfect) combustion.

Spike or Transient or Transient Voltage Surge (TVS): Momentary (less than one cycle) increase in voltage.

Strike: The socket into which a *bolt* slides when locking a door, etc.

Surge: Sudden increase in electrical current; also used for *spike*, because the two often arrive together.

Tempest or Compromising Emissions: Electromagnetic emanations from electrical equipment that carry recoverable information, popularly referred to by the code word for a US government program to combat the problem.

Uninterruptible Power Supply (UPS): Device to provide battery power as a backup in case the primary source of power fails.

INTRODUCTION

Almost all corporations today protect themselves with layered defenses consisting of firewalls, antivirus systems, hardened hosts, and other protections. Even so, security incidents (also called security breaches) sometimes occur.

The firm's on-duty staff may be tasked to handle minor incidents because they can respond immediately and generally effectively. For major incidents, however, such as a major virus attack, a major denial-of-service attack, or the hacking (takeover) of important servers, the firm needs a team approach to stop the breach and get the firm back to normal. To handle major incidents, many firms create computer security incident response teams (CSIRTs), also known as computer emergency response teams (CERTs) and computer incident response teams (CIRTs). The term *computer emergency response team* (CERT) is a registered trademark of the CERT/Coordination Center at Carnegie-Mellon University (www.cert.org) and may be used only with permission.

A critical success factor for any CSIRT is speed of response. During a major security breach, a corporation's operations are likely to be disrupted. This can result in the loss of immediate revenues and the imposition of penalties by business partners and regulators and by a loss in customer or investor confidence.

During emergencies, human beings often are not at their best cognitively. Instead of ensuring that they understand the situation well, they often fixate on a single possible solution that eventually turns out to be fatally flawed. They also tend to make mistakes and work slowly when they are handling complex and difficult tasks for the first time. In addition, teams with members who are unfamiliar with the way their coworkers operate often have communication breakdowns.

Consequently, it is extremely important for CSIRTs to be organized before an incident and to conduct live

rehearsals regularly. Although first attempts may not be satisfactory, live rehearsals will identify problems that can be corrected so that performance is good during real incidents.

Once a real security breach occurs, the CSIRT's work must proceed through a series of well-considered steps (Panko 2004). These are the discovery of an incident and its escalation to the status of major incident, the analysis of the incident to understand it, the containment of the attack to stop the spread of damage, repair to get damaged systems cleaned up and operational, possible punishment of the attacker, hardening of damaged systems against new attacks, and postmortem analysis.

BEFORE THE INCIDENT

Justifying the CSIRT

CSIRTs are expensive. It is important to be able to justify the cost of having one to senior management. It is also important to be able to justify requiring participation from a number of departments, including during live rehearsals, which are very time-consuming.

The normal way to justify a CSIRT is to collect data on the frequency of attacks and the damage caused by attacks. One excellent general source is the Computer Emergency Response Team/Coordination Center (www.cert.org). Other good general sources are SecurityFocus (www.securityfocus.com) and the SANS Institute (www.sans.org). The Federal Bureau of Investigation (FBI) and the Computer Security Institute conduct an annual survey of corporations to assess the frequencies of various kinds of attacks (www.gocsi.com). A good source of data on viruses and spam is MessageLabs (www.messagelabs.com). In presenting summary information to top management, it is good to have data on both general trends and some examples of serious problems caused by incidents in specific corporations.

This information should be combined with estimates of how much major attacks of various types would cost the firm and, if possible, how having rapid detection and containment through the use of a CSIRT could reduce these costs.

Organizing the CSIRT

The first step is to create the CSIRT. Information technology (IT) security incidents can affect several functional groups in a firm. It usually also takes the staff from several functional areas to handle major IT security incidents. Consequently, the CSIRT must draw on several functional areas for its membership (Panko 2004): the IT security staff, the IT staff, functional line managers, public relations, the legal department, and external organizations, such as outsourcers and law enforcement agencies.

The IT Security Staff

Obviously, the IT security staff needs to be involved and may lead the CSIRT. Most firms have very small IT security staffs, and for these firms, it is normal for the entire IT security staff to be on the CSIRT.

The IT Staff

Sometimes, the IT security staff is under the information technology director. This arrangement is not ideal because a large fraction of all IT security breaches are committed by the IT staff. It is better for accountability if IT security is a parallel operation. Another reason for keeping the IT security staff separate is that the IT staff sometimes focuses primarily on technology, whereas the IT security staff must focus more broadly on organizational issues. On the negative side, separating IT security from IT can result in friction between the two groups in terms of the ownership of server logs and other important matters. In addition, a separated IT security staff cannot “order” the IT staff to take action, and separation frees the IT department from accountability for security.

In CSIRTs, it is important to have members of the IT staff be involved, however IT security and IT relate organizationally. It is also important to have operational levels of IT represented as well as IT management because operational employees often have a better picture of what is happening at a detailed level, whereas IT managers have the broader perspective needed to understand what is happening across systems and needed to understand the corporate implications of IT security breaches and alternative remedies.

Functional Line Managers

Fixing an IT security breach is not simply a technical matter. For example, the simplest and most effective way to contain a hacking intrusion is to terminate a victim computer's network or Internet connection. The business implications of “pulling the plug” can be horrendous, however. Functional line managers in critical areas must be involved in and must approve the CSIRT's actions.

Public Relations

One non-IT group that needs to be strongly involved in an adverse incident is the company's public relations

department. If there is a serious problem, the company will want to manage communication with the outside world to cause as little damage as possible to public relations. Under no circumstances should an IT or IT security employee talk to the media directly. Many firms also work with external public relations companies, and there are even public relations companies that specialize in incident handling.

Legal Department

It is critical to have members of the legal department on the CSIRT. Lawyers have the specialized knowledge needed for prosecution and to defend the company against liability. (If an attacker compromises a corporate computer and uses it to attack another corporation, the company whose computer was compromised and used may be liable.)

IT Outsourcers

Most companies outsource at least some of their IT activities, and many companies outsource most of their IT. In such cases, the IT outsourcing vendor will have to work closely with the CSIRT. Beyond that, the IT outsourcer must have good internal incident response capabilities, and expertise in incident handling may be a factor in selecting an outsourcer.

Some firms turn to IT security outsourcers to detect problems in internal systems and to provide expertise and actual work in the case of security incidents. One advantage of using IT security outsourcers is that they have constant experience with handling attacks, whereas internal CSIRTs may handle only a handful of attacks each year.

In any IT outsourcing, it is important to have outsourcers intimately connected to the CSIRT, including participating in rehearsals for security incidents.

Software Contractors

Many information systems today are developed by contractors. In some cases, systems are custom-built. In other cases, they are commercial off-the-shelf (COTS) products. In many cases, they are COTS products customized to a corporation's needs. During an incident, the CSIRT may need help from software developers. The CSIRT should have contact information for the contractors of all major systems, and in the case of pervasive organization-wide tools, such as enterprise resource planning (ERP) systems, a contractor employee may rehearse with the CSIRT during major planning exercises.

Law Enforcement Agencies

Although law enforcement agencies will not actually be part of the CSIRT, their expertise is invaluable if action is to be taken against the attacker. It is important for the CSIRT to understand how to interact with law enforcement agencies and to know what services law enforcement agencies can provide, such as the copying and protection of evidence. Law enforcement officers may even participate in CSIRT rehearsals.

Live Rehearsals

Once the CSIRT is formed, it must engage in rehearsals that take it through realistic emergencies. As noted earlier,

during crises, people are not at their best cognitively. Rehearsals bring the practice needed for correct actions to become habitual so that they will be effective even during the stresses of crises. In addition, you would not expect a football team to execute plays without repetitive practice. In fact, the first time that teams try to execute a play in practice, it is usually painful to watch.

The simplest way to rehearse is to conduct a desktop exercise. In this type of exercise, the CSIRT members sit around a table and are given a series of crisis situations to consider. They then describe each step they would take during each crisis. Desktop exercises are useful during the early stages of a CSIRT's life. During these desk exercises, the CSIRT's members may discover that they are missing representation from an important functional area, that their approaches to recovery are not viable, that they have misunderstandings about authority and terminology, and so forth.

To really develop their skills, however, CSIRTs need to move to live rehearsals, in which they actually conduct the steps needed to address various types of incidents. Live rehearsals identify many problems that the best desktop exercises cannot address. In addition, live rehearsals bring the practice needed for habituated responses and build confidence and speed. The military maintains the importance of "training the way you fight." The same is true for CSIRTs.

Technology Base

The CSIRT will need some technology to do its job. Some of it the firm already has; some must be purchased separately.

Protection Technology

By definition, incidents occur when protection technology (firewalls, antivirus, server hardening, etc.) breaks down. Good protection technology may, however, be able to reduce the severity of an attack. Protections are discussed extensively in other chapters in this book.

Intrusion-Detection Systems (IDSs)

Technologies can also help in the response phase of incidents. Most obviously, intrusion detection systems can alert firms to attacks. In addition, IDS log files can help the firm analyze what has happened during an attack. This chapter does not look at IDSs because they are covered in detail elsewhere in this book.

File-Integrity Checkers

To respond to an incident involving a server compromise, it is important to be able to know what changes the attacker has made. File-integrity checkers periodically create message digests of important system programs. Tripwire is a popular file-integrity checker. After an attack, message digests are again computed and compared with message digests before the attack to see which programs have been changed. Unfortunately, few firms use file-integrity checkers because they are difficult to use successfully. A serious problem with these tools is that many critical system

files change during normal operation. Consequently, it takes a great deal of knowledge to select the specific system files to which file-integrity checkers should be applied.

Evidence-Collection Technology

Evidence-collection technology allows a firm to capture evidence during an attack. If evidence is not collected rapidly and carefully, it will become almost impossible to prosecute attackers or even to understand the attack well. One action is to back up the hard drive on the compromised computer. In addition, transient information stored in RAM (random access memory) during an attack may be crucial to understanding the attack and prosecuting attackers. Special-purpose software can handle backups and capture this transient information in ways that will preserve evidence for presentation in court if necessary. Again, this chapter does not discuss evidence-collection technology because this topic is covered in several chapters dealing with forensics in this book.

The Problem of Communication

One inevitable problem in CSIRTs is communication. During an attack, e-mail may be compromised, and even if it is not, it is likely to be too slow for important functions. The CSIRT organizer must maintain up-to-date lists of office telephone numbers, home telephone numbers, pager numbers, short message service cellular telephone numbers, e-mail addresses, and other contact information for each member of the CSIRT. This contact information changes so rapidly that it must be updated frequently and aggressively.

In the same vein, each CSIRT member must designate an alternate team member if he or she is unavailable. The CSIRT leader needs to maintain up-to-date contact information for these alternates as well. Ideally, alternates should participate in tests.

The Decision to Prosecute

One issue should be considered carefully before any incident occurs: whether to attempt to punish the attacker. For internal employees, this usually is a fairly straightforward decision because termination and lesser punishments are easy and usually legally safe to administer.

For external hackers, however, prosecution is difficult, especially if the attacker is a minor. Furthermore, pursuing prosecution may open up the firm to negative publicity and consequent losses in customer and investor confidence. Before attacks occur, the company should develop a policy regarding external (and internal) prosecution with the aid of the corporate legal department and senior managers.

One consideration in developing prosecution policies is that successful prosecution will require the CSIRT to take certain actions discussed later in this chapter. Evidence must be carefully protected and preserved. In addition, during the attack, it may be necessary to allow the attack to continue long enough to gather sufficient evidence for conviction instead of cutting off the attacker as soon as possible.

DURING THE ATTACK

Although preparation before a security incident is important, how well the CSIRT responds to actual security incidents is the litmus test for success.

Discovery and Escalation

First, the attack must be discovered. Often, the employee who discovers the attack is a low-level IT employee or an employee in a functional area such as marketing. A key question to ask any firm to assess its state of security is, “Do your employees know the telephone number for reporting security concerns?” A sticker with this number should be on every telephone in the organization. Often, this is the telephone number of the firm’s general security office. Delays in reporting suspected security breaches often result in severe damage before the CSIRT can even start its work.

In other cases, someone on the IT security or general IT staff detects the incident. Often, the firm’s intrusion-detection system sets off an alarm when there is suspicious activity in the system.

In addition, the IDS maintains log files of events relevant to security. During the later analysis phase, analyzing these log files is crucial in understanding the nature of the incident.

The on-duty IT and IT security staff members typically handle small incidents. However, the on-duty staff manager must have clear guidelines for when to escalate an incident—that is, when to declare the situation sufficiently dangerous or damaging to convene the CSIRT. In particular, the firm must have good guidelines for classifying attacks as minor or major.

Initial Analysis (Triage)

The first action of the CSIRT must be to analyze the situation. There is a tendency to act precipitously even when little information is available. A short initial period of incident analysis is critical for later success. This is similar to the medical concept of triage (the initial analysis of a patient’s condition) and is, in fact, often called triage.

The first step is to classify the security incident. Typically, there are three types of security incidents—widespread virus or worm outbreaks, denial-of-service attacks, and hacking attacks. Hacking is the access of a protected resource without authorization or in excess of authorization. Hacking, in other words, is breaking into a client, server, switch, router, or other computer.

The second step is to understand the attack. What vulnerability allowed the hacker to break into the computer? What has he or she already done? How sophisticated does the attack appear to be? In the case of virus or worm outbreaks, how is the virus or worm propagating, and how rapidly is it propagating?

Although analysis typically focuses on internal data in computer and intrusion-detection system log files, the CSIRT may also contact other organizations, including the Computer Emergency Response Team/Coordination Center (www.cert.org), which maintains information about common hacking breaches and virus attacks. There is a good chance that the current attack uses a method

that has been common in recent attacks, that the method is well understood, and that there are good defenses and recovery techniques already known.

Containment

The next step is containment, which means stopping the attack. As noted earlier, the simplest approach to containment is to unplug affected computers. Although this is effective and may even prove to be necessary, it is a drastic step that can have important implications for the firm as a whole if an affected server is vital to the firm’s operations. Effectively, unplugging a computer is a self-administered denial-of-service attack.

In addition, it may be desirable to allow the attacker to continue working so that the attack can be better understood. Containing attackers too soon may simply keep them out for a few minutes, after which they may be able to get back in using the same method they used to gain entry in the first place. In a virus or worm attack, containment before understanding may result in immediate reinfection through the same vulnerability.

If legal prosecution is a goal, furthermore, it may be important to continue gathering evidence. On the negative side, if hackers are given sufficient time, they can scatter backdoor attack programs throughout a server’s directories, read sensitive information, and take steps to make themselves difficult to detect. Consequently, containment should be initiated as soon as possible.

Recovery

Recovery, also called repair, means getting the computer system back to the state it was in before the attack. This means removing programs the attacker placed on the computer and cleaning up any altered data files.

Recovery usually focuses on program files, because hackers and virus and worms often litter the computer with attack programs that must be rooted out. Attackers also Trojanize legitimate system programs by replacing them with an attack program but keeping the name the same. To recover the system of program files on the computer, there are three main options: repair during continued operation, restoration from backup tapes, and reinstallation from original installation media.

Repair during Continued Operation

If a company has a good way to recognize attack programs, it may be able to make program file repairs while the computer is still operational. However, this presumes that the firm has done such things as keep message digests for all program files so that changes can be detected. This seldom is done.

Recovery from Backup Tapes

It is more common to reinstall all system and other program files from the last clean backup tape. This can be effective, but it is important to know when the attack began, because the backup files may themselves be suspect. In addition, the restoration of program files from backup tapes often requires the system to be taken offline at least temporarily.

Reinstallation from Original Installation Media

In the worst case, the computer's software will have to be reinstalled using original software installation media. It is important to have these media readily available for such eventualities. It is also important to document all configuration changes made during and since the last installation. For instance, patches frequently need to be applied to remove known vulnerabilities, and there usually are many company-specific and computer-specific configuration changes made for other reasons. Reinstallation from original media typically takes the computer down for several hours.

Data Files

The CSIRT will face special problems if the attack damaged data files. Although restoration from the last clean backup tape will work for older files, all data entered since the last backup will be lost unless a real-time journal of changes has been maintained (which is rare). Laboriously, online files can be compared with backup files to identify safe files and files that must be looked at carefully.

Protection against Subsequent Attacks

The last action of any CSIRT during an attack is to protect the firm against subsequent attacks. Obviously, the specific vulnerability that allowed the attack to succeed must be fixed. In addition, firewalls should be tuned to stop such attacks if possible, and intrusion-detection systems must get filters to warn of subsequent attacks that are conducted in the way the current breach was created.

Second, and more subtly, the server that was attacked must be especially hardened against reattacks. Hardening involves the application of all patches to the system and the general configuring of the system for maximum security.

Internet hackers, to demonstrate their successes, often invite other hackers to get into your system. For some period of time after an attack, your "famous" server will continue to be attacked by hackers. If you repair the specific exploit used in the first place, hackers will attempt to find other vulnerabilities to prove that they could break into the server in ways that the original hacker could not.

AFTER THE ATTACK

Sanctions

Sanctions are punishments that a firm directs at attackers. Although anger usually makes a firm eager to sanction attackers, it is not always practical to do so.

Punishing Employees

If the attacker is a current employee, the firm must weigh the benefits of prosecution against the simple expedient of firing the employee. (For minor incidents, milder sanctions may be appropriate.) Firing an employee typically can be done with no publicity, especially if the employee agrees to either keep quiet or face legal prosecution. In addition, although prosecution is difficult, employment usually can be terminated fairly easily for attacking IT resources, and it usually is legally safe to terminate employment (however, state laws differ in the United States,

international laws vary greatly, and union agreements may make sanctions difficult to apply in some firms).

Prosecuting Attackers

Prosecuting employees, ex-employees, or other, outside, attackers in courts of law requires a firm to prove that a particular person committed the attack. This can be difficult, especially if the attacker is using a spoofed IP address or attacked indirectly from a computer previously compromised instead of from his or her own computer.

In addition, as noted earlier, the attacker must be traced doing a series of actions (individual actions may not convince a jury), and this may require allowing the attack to continue longer than it would if prosecution were not a goal.

Successful prosecution will depend heavily on the quality of evidence collected. As soon as possible, crucial information on the attacked computer must be documented or backed up. Otherwise, the defense will argue that the evidence is tainted and that many things could have caused later changes.

In addition, the CSIRT needs to document carefully how and by whom evidence was collected. The firm also must maintain a clear chain-of-evidence documenting who had the evidence at all times and how it was collected and protected after collection. Any breakdown in documentation can ruin a case. Judges often will not even allow a jury to see evidence that does not meet strict legal evidence requirements.

For prosecution, it is critical to train the CSIRT beforehand in evidence collection and preservation. In fact, it is highly desirable to call in local authorities or the FBI. They can make backups of your hard drives and collect other information in a way likely to get a conviction. Other chapters in this book contain detailed discussions of forensic data collection.

Lawsuits

For attacks that produce only modest amounts of damage, the authorities often are reluctant to prosecute. A firm may still be able to act through the legal system by suing the attacker for actual damages and perhaps for punitive damages as well. These damages and the attacker's cost of legal defense may be a satisfactory way to exact some measure of revenge. However, lawsuits are expensive and reveal the attack to the public. In addition, if the hacker community views the lawsuit as "lame," the firm may become a popular target of revenge attacks by other hackers.

Reprisal Attacks

One option is to attack the attacker in return—essentially, hacking the attacker's computer. This may seem attractive, but it is almost always a very bad idea. First, attackers often use intermediate victim computers to launch attacks. Reprisal attacks are likely to hurt an innocent victim. (If a firm feels that companies that allow their computers to be hacked are not innocent, it should keep in mind that it has just been hacked itself.)

Of course, more fundamentally, reprisal attacks are almost always illegal. The jailing of members of the CSIRT is not a goal of incident response. Also, a CSIRT is an official

organization within the firm; liability for a reprisal attack is likely to extend to senior officers and even the board of directors.

Postmortem Analysis

After things have stabilized, it is important to conduct a postmortem analysis to review what happened during the incident. The goal is to improve future responses to incidents. Things that worked well should be noted, but problems also should be highlighted and fixes created for the future. After the exhaustion of an incident and the need to catch up on work postponed during the incident, it is difficult to motivate the CSIRT team members to undertake a postmortem analysis. However, given the valuable information gained during the actual incident, as opposed to simple live rehearsals, the information gathered in the postmortem analysis can produce strong benefits.

There should also be a follow-up analysis 1 to 6 months later to determine which recommendations made during a postmortem analysis have been implemented and which have not.

CONCLUSION

When major IT security incidents happen, companies cannot sit back and wonder what they should do. Before the attack, companies need to organize and train cross-disciplinary computer security incident response teams—also called computer emergency response teams. Training using realistic rehearsals is important for ensuring adequate and rapid CSIRT responses during an emergency.

During an attack, once an incident is discovered and escalated by the on-duty staff to a major incident, the CSIRT is activated. The CSIRT analyzes the attack so that appropriate responses can be made, contains the attack to prevent further damage, recovers program files and perhaps data files, gathers information needed for internal punishment or legal prosecution, hardens the system to prevent reattacks, and conducts a postmortem analysis to refine its incident response abilities.

GLOSSARY

Analysis: Incident response phase just after discovery phase. The CSIRT determines how the attack was made and what was done to affected systems.

Breach: Another name for a *Security Incident*.

Computer Emergency Response Team (CERT): Another name for *Computer Security Incident Response Team*.

Computer Incident Response Team (CIRT): Another name for *Computer Security Incident Response Team*.

Computer Security Incident Response Team (CSIRT): Cross-disciplinary team created to respond to major security incidents.

Containment: The phase in incident response in which the damage to systems is stopped.

Desktop Exercise: A process in which the CSIRT members sit around a table and discuss in detail the steps each member would take during a response.

Discovery: The phase in incident response in which a security incident is first discovered and reported.

Escalation: The act of determining that a particular security incident is a major breach and that the CSIRT must be activated.

Forensics: The application of science to criminal investigations.

Hacking: Taking over a computer; intentionally using a computer without authorization or in excess of authorization.

Hardening: Removing vulnerabilities from a host computer and configuring the computer for high security.

Incident: Another name for a *Security Incident*.

Incident Response: The multiphase process of responding to a security incident.

Information Technology (IT): Computer hardware, computer software, networking, and data.

Intrusion-Detection System: Tool that signals that an attack appears to be underway and that collects data in log files for analysis during and after an incident.

IT Security: Security of the IT function, as opposed to physical and building security.

IT Security Staff: The IT staff given responsibility for IT security, as opposed to physical and building security.

Live Rehearsal: An exercise in which the CSIRT team members go through a sample incident, implementing each step along the way.

Outsourcer: External company that provides IT services to a firm.

Postmortem Analysis: Assessment conducted after a security incident to determine how to respond better in the future.

Prosecution: The attempt to convict an attacker in a court of law.

Public Relations: Department in a firm charged with communicating with the public and the media on behalf of the firm.

Punishment: Taking action against an attacker; both sanctioning employee attackers and prosecuting and suing external attackers.

Repair: Phase in incident response in which the damaged system is brought back to correct operation.

Reprisal Attack: Attacking the attacker (usually illegal).

Security Breach: Another name for a *Security Incident*.

Security Incident: A virus attack, denial-of-service attack, or hack (computer break-in).

Trojanize: To replace a legitimate file by an attacker's file, giving the attacker's file the same name as the legitimate file.

INTRODUCTION

As organizations work to determine how to protect their data, they face the challenge of quantifying the value of their data, then determining the most effective way to back up their data so that it can be restored in an acceptable time frame if a disaster occurs. This chapter addresses issues important to identifying backup and recovery requirements.

GENERAL BACKUP AND RECOVERY REQUIREMENTS

Requirements Planning Team

Planning for backup and recovery activities is often done in the context of a disaster-recovery planning project. The requirements for backup and recovery systems have technical, logistical, business, and operational components. Because the potential impact of any data loss is so broad, the planning for backup and recovery requirements should involve a cross-functional team. Candidates for the planning team include computer operators, application developers, key customer representatives, physical security personnel, database administrators, and stakeholders in the organization. As with any successful IT project, the support of an executive sponsor will greatly increase the likelihood of developing a robust backup and recovery system (Schiesser 2002, 300–4).

Operating Systems

One factor that influences every aspect of the backup and recovery process is the operating system. Operating systems dictate the terminology, thought processes, and operating procedures used in any IT environment. The operating system is the foundation on which backup and recovery system requirements are built.

There are a few areas in which the backup and recovery system requirements will be similar regardless of the

operating system in use. These areas include job scheduling, scripting, and native backup utilities. Regardless of the operating system, most backup systems require a job scheduler to automate the backup process. This ensures that backups are done at the proper time and with the proper frequency. Job schedulers provide similar features across platforms and allow administrators to verify that backups are running on schedule. Every operating environment provides a means for creating scripts or sequencing commands as part of a backup procedure. The terminology for this process may be a script, a job control language program, or a batch program, but in many operating environments, the script is used to start the backups. Another similarity among operating systems is that each provides the administrator with utilities or commands that are specific to the operating system, and may be used for creating backups. These operating-system-specific utilities are sometimes used by third-party vendors as the basis for creating backups. An example of this is AMANDA, the Advanced Maryland Automated Network Disk Archiver, a public domain utility developed at the University of Maryland. AMANDA uses the UNIX tar utility to facilitate partial backups on systems running UNIX (Preston 1999).

Data Types

Different types of data hold different levels of value for the organization. Mission-critical data should be backed up frequently, and other data vary in value from important to unnecessary and may require a lower backup frequency (McDowell 2001). To develop backup and recovery system requirements, it is essential to understand the value of different data types. Assessing the current storage requirements will help to determine backup needs, appropriate methods, and the most effective strategies for backup and recovery procedures. As various data types are evaluated, the amount of each type of data on the system, along with the volatility of the data type should be documented. Volatility refers to the frequency with which data change or

Table 1: Data Type Assessment

Data Type	Size in Megabytes	Volatility	Value to Organization
Operating system		Low	High
Database		Medium to high	High
Applications		Low	High
E-mail		High	Medium to high
User files		Medium to high	Low-medium to high
Log files		High	Medium
Other			

are added to or deleted from the database. Data that do not change frequently, such as archived files, could be described as having low volatility, while files that are updated hourly would be considered to have high volatility. Table 1 is representative of the types of data that could be considered in a storage requirements assessment.

Another benefit of the storage requirements assessment is that obsolete data may be identified in any of the data types. Cleaning up obsolete data before determining backup requirements will provide a better picture of overall backup needs (Barth 2004). Archiving data implies that data have been moved from dynamic production databases to a static system. The static system will require different backup and recovery strategies because it changes less frequently (Mensing and Corbitt 2004).

One way to estimate the value of data is to determine how much effort would be required to re-create the data if they were lost. A similar approach is to estimate how much time and effort has been spent to create the data that are stored on a given system. Either of these approaches can provide insight into the true value of a data set to the organization (Wells 2003, 538). In addition to determining the value of data, one should also consider how critical certain systems are to ongoing operations. Data that may be easily created may appear to have a lower value, but if the data are critical to operations, the value increases (D'Amico 2004).

Databases

Most organizations consider the information stored in their databases to be among their most valuable assets. In some organizations, the database information is a key component of daily operations. Organizations such as financial institutions rely on their databases to provide critical information for almost every transaction. The critical nature of this information store requires careful planning to mitigate the risk of loss of the data. The simplest way to backup databases is to copy the entire database to backup media; however, this method can be time-consuming and expensive for large databases. More frequently, databases are backed up using a full backup followed by incremental backups or differential backups during a given period (Qian, Nakamura, and Nakagawa 2002).

Security Data

Different operating systems provide various capabilities for backing up sensitive information such as user IDs,

passwords, permissions, and group memberships. Backing up these data is vital to the system backup, and sometimes overlooked. A complete backup plan should include provisions for backing up security data, along with guidelines about how the media should be handled, and how the restoration will be executed. Many organizations back up the security data in tandem with the operating system backup.

E-Mail

E-mail is an area in which backups are sometimes confused with archives. Archiving e-mail is the process of moving e-mail messages from the e-mail system to a record-retention system designed to archive electronic documents and messages. This is in contrast to backups, which are created to mitigate the risk of the loss of the data in the event of a disaster. Some experts recommend that e-mail be kept in the e-mail system for a minimal amount of time, then moved to a permanent archival system (Stephens and Wallace 2000). One of the legal concerns of backing up e-mail is the potential for electronic discovery. Electronic discovery is a request from a court of law to produce electronic documents for participants in a lawsuit. If an electronic discovery request is made, the company must make all e-mail messages available for inspection. The e-mail messages that exist on backup media are also subject to an electronic discovery request (Lange 2002).

User Files

User files may be overlooked or ignored in the backup plan of a data center because they exist on computer hard drives in each user's machine. One approach to backing up user files is to make users responsible for their own backups. User files saved to a file server are more likely to be backed up on a regular basis because they are readily accessible via the network. The analysis of user files should include a review of the file types and age of the files. Most users do not delete files unless they are prompted to do so because of disk quotas or other policy requirements. Asking users to remove documents they do not need can streamline the backup process. User files should also be analyzed to determine whether their existence on the network complies with company policy. If company policy prohibits storage of music files such as MP3 files, then these files will only impede the backup and recovery process without adding value to the data backup and restore process (Barth 2004).

Log Files

When assessing data types in an information system, it may be difficult to assess the value of certain data types. Log files are a typical example. Log files that were produced during a software installation process that occurred in the distant past may need to be purged from the system, while other log files should be treated with care and an eye toward preservation. In some cases, organizations may be required to analyze and retain log file data to comply with regulatory compliance rules such as the Sarbanes-Oxley Act (Zhen 2005). Log files are also variable in volatility. They may contain information about a single event, such as a software configuration change, or information that is updated by the system on a regular basis. Evaluating the backup requirements for log files is likely to require input from technically adept staff members. Finding the balance between backing up all log files and backing up only the most critical log files is a challenge that should be addressed in the context of a limited backup window and the need to meet the business and regulatory requirements of the environment.

Configuration Data

Many of the files on any computer specify how the computer functions. These files are normally backed up along with the operating system files or the security data. It is important to note that configuration files may also reside on network devices. Each piece of network hardware—such as switches, routers, and hubs—contains tables, configuration information, and security information that are critical to network operations. This configuration information is normally not highly volatile and may only be changed when new equipment is added or existing network configurations are updated. A system to back up these data should be considered as part of the overall disaster recovery plan, and the requirements for backup and recovery of network components are different from the requirements for other types of data. If an organization has previously ignored the backup and recovery issues for network devices, then the steps below may be used to develop an initial starting point for protecting this critical data.

1. Inventory network equipment: In many organizations an inventory of network components has already been done. Usually the purpose for such an inventory is to track the value of each component as a financial asset, or to monitor network performance to aid in troubleshooting network problems. Using either of these types of inventories is an excellent starting place.
2. Determine backup needs: The most important aspect of the inventory for backup and recovery requirements planning is to determine whether there are configuration data that need to be backed up on each device. The next most important piece of information is the actual function of the device. An Ethernet hub may not contain any special configuration data, but its existence should be documented so that in the event it is destroyed, the physical network configuration can be recreated. A network switch is more likely to have specific information about network segments, Internet protocol

(IP) addresses, and traffic routing that should be saved in the event that the switch is destroyed.

3. Create initial backups: For devices that have custom configuration information, create initial backups. Many devices provide the ability to copy configuration information to a personal computer, where the configuration file can be modified, copied to external media, or printed.
4. Specify backup format: One of the risks associated with network equipment is that a replacement unit may not use the exact same configuration format that the original unit used. In fact it is very likely that any replacement for network equipment will be significantly different from an original unit. Network technology advances at high speed, and the improvements are incorporated into new products frequently. Because of this risk, it is prudent to consider creating backup documentation for certain network equipment other than simply backing up the configuration files. The meaning of the configuration parameters for a complicated switch should be committed to a designated format so that in the event the equipment is destroyed, and the replacement is significantly different, the new equipment can be configured to operate effectively in its new environment.
5. Handle with care: Keeping a duplicate copy of the configuration files and associated documentation on a personal computer is a good first step. Backing up these configuration files and storing them in a secondary location can further reduce the risk of loss.

The requirements for continued backup and recovery of network devices should be determined based on the volatility of the configuration files. Two approaches to backing up this type of data are the periodic approach and the change trigger approach. In the periodic approach, backups are created based on set time periods. Weekly or monthly backups are created; documentation is updated, backed up, and stored in an alternate location. In the change trigger approach, any time a network device configuration is changed, or new equipment is installed, the backup process is triggered.

It is difficult to plan all aspects of restoring data to network components. The major reason for the difficulty is that network components are frequently replaced by more advanced components with added features and different capabilities. The part of the plan that can be successfully created is the retrieval of all configuration information from the backup documentation. If the configuration files can be used by the new equipment, then the recovery will be faster, but if the replacement equipment requires information in a different format, or new specifications, then the alternate documentation must be used to initiate the new device. The Network Reliability and Interoperability Council (NRIC), an organization comprised of telecommunications industry representatives, has developed over 750 best practices that deal with backup and recovery of telecommunications equipment. These procedures address a variety of issues in network reliability and promote automated backup procedures for telecommunications equipment (Lennert et al. 2004).

Recovery Requirements

Because backups usually occur frequently and recovery occurs much less frequently, many organizations put more effort into the backup process than into the planning of the recovery process. Both are important. A poorly planned recovery process can make a great backup plan look terrible, because the backup is only half of the overall process. To determine the requirements for the recovery system, some critical measures must be analyzed.

The first is the recovery time objective (RTO). RTO is a measure of how long the organization can effectively function without the system. If the system is a convenience system that is only used for occasional reference, then the organization may be able to function for days or weeks without access. The RTO for such a system might be expressed in days. If the system is a mission-critical, real-time, transaction-oriented system that the organization relies on to do business 24 hours a day, then the RTO might be expressed in seconds. Determining the RTO for each system is important, because these numbers will ultimately contribute to the recovery requirements for the organization.

Another measure that should be determined for each system is the recovery-point objective (RPO). RPO is expressed in terms of how much data the organization can afford to lose if the system fails. Less volatile systems generally have a higher RPO than more volatile systems. Mission-critical, online systems usually have an RPO that approaches zero (Preston 2005). Recovery issues need to be addressed in planning the backup strategy. RTO and RPO measures will influence the way backups are scheduled and executed.

A COMPARISON OF BACKUP METHODS

Hot versus Cold

The hot or cold approach to backups is directly related to the system availability requirement in the organization. Hot backups are those that take place while the system is operating; cold backups take place while the system has been made inaccessible to users. If an organization cannot tolerate any down time, then a hot backup scheme is usually implemented. In a hot backup scenario, data may be copied to a fast tape drive or secondary disk while data files are actually in use. This may require data to be buffered and databases to take advantage of journaling, and it may slow down the overall performance of the system during the backup process. In a cold backup scenario, the backup window is normally defined as a time when minimal usage is likely such as in the early hours of the morning—for example, 2:00 A.M. Shortly before the scheduled backup time a notice may be sent to any users logged on the system informing them that the system will be going down for scheduled backups. At the appointed time, interactive users are logged out of the system and batch programs are ended or suspended. When all interactive processes are stopped, the system is identified as a “quiet” system and can be backed up. The backup is then executed and verified before allowing users to log in to the system. This sequence is important because if one of the tapes cannot

be verified, the backup set may be corrupt. The following checklist shows the correct sequence of events in a cold backup scenario:

1. Notify any users on the system that the system will be unavailable beginning in a set amount of time (usually 10 to 15 minutes).
2. At the scheduled time, disable the ability for users to log into the system interactively.
3. At the scheduled time, remove any users from the system who have not logged out.
4. Start the backup job at the designated time and monitor the job for successful completion.
5. Verify the readability of the tapes or other backup media.
6. If the backup media prove to be readable, then allow users to log in. If the backup media fails, take action to redo the backup or log that the backup media failed. (McDowell 2001).

Online versus Offline

During recent years, changes in telecommunications technology have allowed some new backup methods to thrive. Improvements in the quality of service, bandwidth, and cost of telecommunications have made it possible to backup computer systems over telecommunications links. This is referred to as an online backup. Online backups are becoming more cost-effective when compared to the traditional method, in which all of the costs of the traditional method are considered. Traditional backup costs include tape drives, media, personnel, off-site courier expenses, and physical storage space. Expenses for online backups include the telecommunication link and associated hardware, along with a service provider's software and service fees. In many cases an existing telecommunication link is used, provided there is enough available bandwidth. One concern that should be addressed is the security of sensitive data traveling over telecommunication lines. If data are encrypted before being sent, the security issue is handled, but encryption requires CPU cycles and will consume system resources on the system being backed up (Stoddard 2004).

Backup Types

There are several types of backups that can be performed with any data type. Three commonly used backup techniques are the full backup, the incremental backup, and the differential backup. The full backup captures all of the files specified in the system or subsystem. These files are stored on a single media set, and this type of backup provides the fastest and cleanest restore scenario. The negative aspects of the full backup are that it takes more time to perform than other types of backups and in some cases files are backed up that rarely or never change, resulting in unnecessary media storage requirements.

An incremental backup establishes a repetitive cycle that begins with a full backup, then on subsequent periods (usually days) backs up only the data that have changed since the last backup, including previous incremental backups.

The backups made after the full backup normally require fewer media, less time, and less computer resources than the full backup. The negative aspects of this strategy are that the restoration process may require multiple media sets, and the time to restore data will be longer than the full-backup method. For example, suppose a full backup is run on Monday, followed by incremental backups on Tuesday and Wednesday. On Thursday morning the server crashes, requiring a new disk to be installed. To restore the system the full backup set would have to be restored, then the media set created on Tuesday would have to be restored, followed by the Wednesday media set restoration. Therefore the time required for restoring the data increases as the time since the last full backup increases.

A differential backup also begins with a full backup, then in subsequent periods, backups are run to back up any files that have been created or modified since the last full backup. This method may require fewer media sets to restore data because all changes since the last full backup are saved in each subsequent backup. In the scenario mentioned above, the Monday backup set would have to be restored, and then the most recent differential backup would have to be restored. This would result in a more streamlined restore process than used in the incremental strategy (Swanson et al. 2002).

Generational backups refer to a system of media rotation in which three media sets (usually tapes) are used for backups. Typically the first set (set A) is referred to as the grandfather, the second set (set B) is referred to as the father, and the third set (set C) is referred to as the son. Set A normally consists of a full backup tape(s) and all incremental or differential tapes used until the next full backup is scheduled. When the time to create the next full backup occurs, set A is set aside and set B is used for the next rotation. In the third cycle set C is used for the full and subsequent incremental or differential backups. In some cases, set A is then reused for the next cycle, and in some cases the grandfather (set A) is permanently retired and archived in an off-site location. One benefit of this practice is that if one media set is corrupted or damaged, then the previous media set still exists and can be used to recover the data, although it may not be as up to date as the most current media set (Marakas 2006, 303).

SOLUTION OPTIONS

Since the majority of computer systems are a mixture of heterogeneous systems, the requirements for any single organization are likely to be a mixture of methods and techniques that support the individual organization. In this section several issues are discussed that highlight concerns in diverse environment.

Third-Party Backup and Recovery Product Requirements

There are many backup and recovery tools on the market. Several of these tools provide the user with options that are beyond the capabilities of their operating systems and offer excellent value by improving the backup and recovery process. A complete evaluation of third-party backup software is beyond the scope of this chapter; however,

a discussion of some of the important features that are available is in order to provide some insight into how to evaluate various backup and recovery packages. The following checklist can be used to evaluate potential backup and recovery software. Requirements for specific organizations may be more or less rigorous than those listed, but this checklist should provide a good starting point for any product evaluation.

1. **Easy installation and configuration:** The product should be easy to install and configure. If the configuration is overly complex, the risk of improper configuration rises and along with it, the risk of getting an incomplete backup rises proportionally. This issue increases in importance when an entire system is lost and the backup software must be reinstalled to do a complete restore. If the installation process is complicated and lengthy, the recovery time will be extended.
2. **User interface:** The user interface for a backup and recovery tool should be easy enough for a user with limited training to use. Some of the tools available allow the user to select wizards to streamline various processes, and others require a step-by-step sequence of menu options. Remember that the recovery may be performed by someone other than the most highly trained operations staff, and in some cases under difficult circumstances. A simple user interface can make the restore process easier and increase the likelihood of success for a backup and disaster recovery team member.
3. **Support:** Support for backup and recovery software may be available via online documentation, a built-in help facility, printed manuals, or via e-mail or telephone. One way to test the response of a vendor is to call the help line prior to buying the software and evaluate the response prior to purchasing the product. If you have to navigate complicated electronic response screening software before speaking to a live support person, you should know that before the purchase. Evaluating the overall help features of a product is important in determining whether the product is well supported.
4. **Multiple device support:** Many backup and restore products support specific drive types and not others. Another related issue is that you may be backing up on tape today and DVDs tomorrow. The best products support many backup devices and have the ability to span across multiple media to create a media set.
5. **Validation:** Most backup products provide validation for the external media. An important consideration regarding validation is the time required for the validation process. Some organizations opt not to validate the backup media because of the time it takes. This risky behavior reduces the chances of a complete and accurate backup. The time required is a function of the speed of the backup device, but the software can function efficiently or poorly in validating the integrity of the media.
6. **Compression:** Backup and restore software usually provides the ability to compress data before storing it on the backup media. This reduces the number of tapes required, but may extend the time required for the backup and slow down the system during the

backup process. This feature may be important depending on the backup method chosen and the speed of the processor.

7. Encryption: The ability to encrypt data provides an additional layer of security for the organization's data. Some organizations protect their computers effectively with authentication, physical security, and other safeguards, but do not consider security as important for their backup media. This mistake can be avoided by encrypting backup data.
8. Reporting: Backup and restore software should provide reporting for problems that occur during the backup or recovery process, successful operations, and configuration information. The reporting information should be easy to understand and as jargon-free as possible. A lack of robust reporting features is a good reason to avoid certain third-party backup products.
9. Flexibility: Backup and restore software should allow files to be backed up from selected locations, volumes, and in groups defined by the administrator. It should support full backups, incremental backups, differential backups, and on-demand or ad-hoc backups. The software should also support restoring single files from a backup media set, and restoring files to any location.

Third-party backup and restore software vendors offer numerous products that will effectively manage the backup and restore process. It is important to evaluate an organization's specific needs to determine which product most closely meets those needs. In addition to evaluating product literature, the organization should evaluate independent product reviews that are frequently available in trade publications or magazines (Vella 2005).

Media

Regardless of the platform, operating system, or data type, when backups are performed on any removable media (such as magnetic tape or CDs) the procedures for handling the media should be documented. Removable media may be kept on-site or off-site. If the media are stored off-site, the storage facility needs to be physically secure, environmentally controlled, and accessible during potential

recovery windows. Contact information for the off-site storage facility should be available to IT staff who may require the media to restore files during and after normal business hours. The off-site storage facility should be far enough away from the data center that potential weather or other disasters would not affect both locations and therefore reduce the potential for recovery. Table 2 is a planning checklist for media requirements. The checklist is designed to help determine how much media is required for individual backup situations. The checklist assumes a full backup weekly, followed by incremental backups on a daily basis. The table should be modified to reflect specific backup strategies.

Tape versus Disk

Magnetic tape is still one of the most popular media for backing up information systems. It is relatively inexpensive, based on proven, stable technology and supported by numerous hardware and software vendors as a viable backup technology. Magnetic tape also has some drawbacks. One of the primary drawbacks of using tape is that data recorded to tape is recorded and retrieved sequentially. This can extend the time required to find and retrieve single files on a tape or tape set. Another drawback is that tapes tend to wear out with use, and a worn tape can be unreliable. Various vendors provide software to verify the contents of a tape after it is written, and this improves reliability, but errors may still occur. Even when a tape has been recorded and verified, a break in the tape can render the tape or the tape set useless. These are some of the disadvantages or risks of using tape, but with these risks noted, using tape is still a widely accepted method for backups.

Another option for saving important data is to copy the data to disk-based storage on another system or subsystem. This may be accomplished using a variety of techniques such as network-attached storage (NAS) or storage area networks (SANs). These technologies are discussed later, but in contrast to using tape as a storage medium, their common advantages will be noted here. The most important advantage of storing the data to disk instead of tape is a faster rate of transfer. Transfer rates for disk-to-disk copies are significantly faster than for disk-to-tape. This can

Table 2: Media Requirements Planning Checklist

A	Total amount of data to be backed-up (full backup)	115 Gb
B	Capacity of individual media (assume tape)	40 Gb
C	Tapes required for full backup	3
D	Tapes required for incremental backup (estimated average per day * 4 days)	$(1 * 4) = 4$
E	Number of generations of tapes	3
F	Total number of active tapes $(C + D) * E$	$(3 + 4) * 3 = 21$
G	Tapes in reserve (in case of tape failure)	4
H	Tapes required for monthly archive	2
I	Total number of tapes for backup system $(F + G + H)$	$(21 + 4 + 2) = 27$

reduce the amount of time required for both backup and recovery processes. Transfer rates are also impacted by the speed of communications between the source of the data and the target storage device. Most experts recommend that a dedicated network be used to transfer backup data between servers and backup devices. This allows maximum throughput and reduces the potential for slow-downs on networks that are used in normal work environments. Disk access is not limited to sequential access methods. Any file can be restored without having to read through other files in the backup set. This is significantly better than searching a ten-tape set for a file that may be located on the eighth tape in the set (Qu et al. 2004). A disadvantage of storing backup data on disk is that it is not usually practical to store the disk off-site. If the target storage disk is in the same physical data center, then some significant risks are still unaddressed. These risks include fire, tornado, flood, and other natural phenomena that can impact the data center. To address these risks, some organizations take advantage of both disk-to-disk backups and tape backups. This can be done by backing up the system using disk-to-disk technology and taking advantage of the shorter backup window, faster transfer rates, and more convenient restore methods, then backing up the target system to tape. The tapes can be made without interrupting online availability of the production system because they are backing up the backup system. The tapes can be moved off-site to mitigate the risk of natural disaster in the data center.

Other Media

Media other than disks and tapes are used in some backup scenarios. These include CD drives and flash drives. Organizations must evaluate the cost and capacity of each of these media to determine whether they are viable options for backup media.

CD-ROM media is a type of CD that may be used as a backup media. ROM is an acronym for read-only memory. If CD-ROMs are used to backup data, then the media may be used only once. The CD-ROMs must then be stored and kept until it is determined that the data are no longer viable as a backup. A similar alternative is CD-RW (read/write) technology, in which the CD may be used multiple times. Since the media can be used multiple times, the cost of this medium is much less than CD-ROM technology. Another alternative to CD technology is DVD, which is also available with read-only or read and write capabilities. DVD drives provide larger capacity than CD drives. DVD media may hold up to 50 Gb of data, whereas CD drives commonly hold 850 Mb of data. Flash drives (also called thumb drives or USB drives) may be used in certain cases for backups. These devices typically plug into an open USB port and appear to the system as a disk drive. The capacity for these devices is constantly increasing, and their potential for use in backup scenarios increases as the capacity increases. One advantage of a flash drive is that it has a small physical size and is therefore easily transported. Another advantage is that no special software is required to install the drive on a different machine in the event of the loss of a computer. These advantages also become disadvantages when considered in light of data

security. The small size would potentially allow the data to be more easily stolen, and the ease of getting the data off of the flash drive by simply plugging it into another computer exposes the organization to increased risk of loss. These risks can be mitigated by using encryption, which is discussed in more detail later in this chapter.

Desktop Computers

There are some specific steps that can be taken to clarify the backup and recovery requirements for desktop systems. The first step is to encourage individual users to participate in a standardized scheme of file storage on their desktop computers. As an example, Microsoft has created standard folders for each user such as My Documents and My Pictures. If every user stores their documents under this (or another standard) scheme, then the backup process can be simplified. Desktop computers may be backed up via network connections, or by using removable media on each computer. Network backups are more consistent because they are usually administered by IT operations. If individuals are responsible for backing up their own desktop computer, they should be trained in the process and understand how to back up their files, along with being told why it is important to do so. Another practice that streamlines the backup and recovery process is to standardize hardware and software for the organization's desktops. Most organizations attempt to standardize as much as possible, but inconsistencies in desktop computer models and brands contribute to complexity in developing an effective backup and recovery system (Swanson et al. 2002). The goals of an effective user training program should include providing the user with an understanding of the organization's approved backup and recovery methods and tools, an introduction to the media supported by the organization's policies and procedures, and access to a list of parties to be notified in various cases of data loss.

File and Application Servers

Some of the same considerations for the desktop environment apply to file and application servers. Standardization for hardware, software, and peripherals can reduce the time needed to recover from equipment failure. One of the key differences between the server and the desktop computer is that many servers are equipped with redundant components such as power supplies, disk arrays, and tape drives. Servers may also be configured with an uninterruptible power supply (UPS) to allow the system to operate during a power outage.

A common redundant component is RAID technology. Using a redundant array of inexpensive disks (RAID) is a way to create real-time backups. Although a full discussion of various RAID levels is beyond the scope of this chapter, a brief description of RAID will help in understanding how RAID may fulfill some of the organizations backup and recovery requirements.

Mirroring

Mirroring occurs when a system is equipped with two different disk drives or disk arrays. When data are written to one disk, they are automatically and immediately written

to the other disk. This creates two copies of all data. If one disk fails, the other disk can provide access to the data. In many cases, mirrored drives are hot-swappable, meaning they can be removed and replaced without interrupting system activity. Once the new drive is installed, the two drives are automatically synchronized and no other intervention is needed. The danger of this type of technology is that it gives some IT managers a false sense of security. Since events may occur that can render the server inoperable, a backup on removable media will further reduce the risk of losing the data. Mirroring is also referred to as RAID Level 1.

Parity

Parity is a technique that is used to determine whether data have been lost. Parity is created by summing the number of bits in a given data stream then adding a parity bit of 1 or 0 to make the sum odd or even. A system may use even parity or odd parity. In even parity the bits are summed then, if the number is odd, 1 is added to the sum to create even parity. The RAID system can determine whether there is damage to the file if the parity is supposed to be even, but during recalculation, determines that the parity is odd. In a RAID configuration, several types of parity schemes are possible. Parity requires multiple drives and does not store a complete second copy of the data as mirroring does (Dean 2006). This popular technique is a safeguard against losing a single disk drive on the server.

Striping

Striping improves performance by distributing data across multiple drives. RAID techniques use a variety of striping and parity techniques to achieve different levels of speed and redundancy (Swanson et al. 2002). Striping data across multiple drives is used in RAID Level 3 (see Figure 1). RAID Level 3 uses a disk controller to write

data for a given file across multiple drives and then writes the parity information on a separate drive. The advantage of this technique is that it provides a high transfer rate and can automatically detect and correct errors related to data storage.

RAID Level 5 is similar to RAID Level 3, but instead of storing the parity information on a separate drive, the parity information is stored on multiple disks in the disk array (see Figure 2). This technique provides a higher level of fault tolerance and is a popular technique for data protection.

Outsourcing Backup and Recovery Functions

Many organizations are looking for ways to streamline technical processes while continuing to meet their organizational objectives. An option that is popular for some organizations is to outsource certain IT functions to a third party. This is frequently done for Web-site hosting because of the intense requirements of the Web hosting environment. Many of the requirements for backup and recovery functions can also be met with outsourcing. Foskett and Tobin (2005) describe three basic mechanisms for outsourcing backups as insourcing, online backup, and hosted backup services.

Insourcing refers to inviting a qualified vendor to manage the backup process using the resources of the organization. The benefits of this approach include maintaining physical control of the data and media and taking advantage of expertise in backup and recovery management without the overhead of having full-time operational employees. This service is available with various amounts of actual on-site support and may include some remote monitoring of the backup process.

Online backups are usually an effective choice for smaller organizations. In this scenario, the data are transferred (in an encrypted format) via telecommunications

Figure 1: RAID 3

Figure 2: RAID 5

systems (usually the Internet) and stored in a remote location. This option is attractive for smaller organizations because they can take advantage of professionally managed backup services without the investment in infrastructure that might otherwise be required. The disadvantage of this option is that when the time comes to restore the data, connectivity and coordination with the service provider must be fully in place.

Hosted backup services are described as backup services for organizations in which most or all of the IT functions are already hosted by a third party. This option is easily selected when the majority of IT operations are hosted off-site because retaining this complex function in-house when the data are elsewhere is difficult to justify (Foskett and Tobin 2005).

There are variations on each of these three themes, and when an organization is considering their options, each of these should be considered. Telecommunications technology advances continue to create new options for moving data from point A to point B, and improvements in outsourcing options are likely to make these and other techniques more attractive as technology improves.

In the broader context of disaster recovery, whether an organization uses in-house employees or contracted third-party vendors for backup and recovery services, there are some services that will usually be performed by an outside company. These services include electrical contractors, water-removal specialists, tree-removal services, and data-recovery services. In documenting the backup and recovery requirements, a list of service providers and their contact information is an important part of the disaster-recovery plan (Erbschloe 2003, 169).

Snapshots

When traditional methods of backup are no longer sufficient, there are some newer technologies that may provide the necessary speed to restore large volumes of data without the expense of long backup windows. One such technology is the snapshot. A snapshot is a virtual copy of a file system that includes all the data in the given file system. The virtual copy of the file system must be backed up to recover from physical failures, but creating a snapshot of a file system will allow for a very short recovery window in many types of failures. The network data management protocol (NDMP) and Microsoft Corp.'s Volume Shadow Copy Service (VSS) are examples of products that support snapshot capabilities (Preston 2005).

NAS and SANs

During the early 1990s, organizations began adopting the client/server model of computing, in which desktop PCs were connected to file servers. This configuration allowed users to store important files on the server so that backups could be centralized and managed. The next step in storage innovation was the movement of storage devices onto specialized appliances directly attached to file servers. This network-attached storage (NAS) took advantage of the widespread availability of various protocols such as Novell's Network File System (NFS). NAS systems are normally deployed using tools and utilities supplied by

the vendor (Morris and Truskowski 2003). NAS may also provide a centralized storage location from which backups can be completed.

Advancements in storage technology have resulted in a system of hardware and software components that interconnect file servers and storage systems (Zheng, Wang, and Zhang 2003). This technology is referred to as a storage area network (SAN). The interconnection may be over an existing data network or via a separate physical network, but is usually high-speed and frequently based on fiber-optic connections. SANs take advantage of multiple storage subsystems by pooling the storage area and allowing multiple file servers to use the free space available on the SAN (Sarkar et al. 2003). Although SANs are sometimes touted as sophisticated storage solutions, the sophistication may also mean complexity. Radding (2005) cites issues such as interoperability problems, latency, and a lack of robust design tools on the market as reasons for SAN adoption roadblocks. Both NAS and SAN technology are attractive for purposes of identifying backup system requirements. The fewer physical data storage devices that contain data to be backed up, the easier it is to plan for how, when, and why the data will be backed up.

Encryption

Many organizations maintain information in their computer systems that represent large investments of time, money, and effort. In addition to the value of the information, some data may be sensitive in terms of Human Resources, or competitive strategies. Most organizations protect their information systems by granting access permission to those members who need access to perform their duties and denying access to everyone else. This approach works well when the data are locked up in a secure data center with limited physical access. The authentication process can break down when the organization's valuable data are stored on removable media such as tape. The size of a tape cartridge makes it easy to carry off-site, thus protecting the organization from the risk of loss due to fire, flood, or other natural disasters. This same feature also provides an easy target for removing critical data from the organization for someone with sinister motives. In some cases, it is much easier to remove a backup tape from the company than to break into the computer system.

One of the ways that some organizations have addressed this risk is by encryption. If the data on a backup tape are encrypted, then in the event it is lost or stolen, the data will still be secure. The majority of organizations do not encrypt their backups, but a trend toward targeting backup tapes for theft is causing concern among those who are required by government regulators to protect their data (Lock 2005). Two of the methods used for encryption are encryption on the data as it resides on the system and encryption done at the time the backup is created through software or hardware. When data are encrypted on the system through database encryption or through an operating system utility, then the data will be encrypted on the tape, meeting the objective of a secure tape. This approach provides an additional layer of security during operation. A drawback of this approach is that

ongoing encryption of a database or data files can be expensive in terms of CPU cycles. Some organizations do not want to encrypt their data on the system, but want to encrypt their backup tapes to reduce the risk of losing their data because of theft (Haber 2005). Encrypting the data on the tapes can be accomplished using software utilities, or hardware appliances. Many software utilities provide encryption capabilities. Third-party backup software may allow the administrator to select the type of encryption and key length among the options for encryption. This type of encryption may require significant computing resources, and it can potentially lengthen the backup and recovery time requirement. Another option is to include an encryption appliance in the system. The encryption appliance sits between the computer system and the tape drive, and encrypts (or decrypts) the data as they are passed from one device to the other. Since the data are encrypted by the appliance, fewer CPU cycles are required of the host system, speeding up the backup process.

One reason that this approach is not widely used is that administrators are concerned about the possibility of not being able to restore the encrypted data. In the event that fire destroys the data center, careful planning must be in place to make sure that encryption keys are available to restore data from backup tapes. If an external appliance is used, then provision for replacing the device and its hardware key are important to recovery. These issues add complexity to the disaster-recovery requirements and must be weighed against the risk of losing the information on backup tapes.

CONCLUSION

Many organizations rely on their data to effectively run daily operations. Because the value of data in most organizations is so high, safeguarding the information is vital to the organization's existence. One important aspect of making sure information is available to users is the backup and recovery systems that ensure data availability, even when computers or network hardware components fail. The requirements for an operational backup and recovery system are built on the foundation of a data and systems assessment. A data assessment identifies and documents various data types, the systems using the data, and other critical system elements such as the operating system and security data. Once the data that need to be protected are identified, the method for backup and recovery can be selected from numerous technologies and procedures. Choices for backup and recovery techniques include third-party solutions or internal solutions, media determination, and frequency determination. Some areas that may be overlooked include backing up network hardware configuration and data residing on desktops throughout the organization. Determining the requirements for backup and recovery systems will help mitigate the potential loss of data for many organizations relying on information to run operations.

GLOSSARY

Data Compression: Storing data in a format that takes less space than it would take under normal storage conditions.

Differential Backup: A backup procedure that copies files that have changed since the last full backup.

Encryption: The process of encoding or obscuring information so only a person (or computer) with the key can decrypt the information.

Full Backup: A backup procedure that copies every file on the system to another media or disk regardless of whether the files have changed since the previous backup.

Incremental Backup: A backup procedure that copies files that have changed since the last backup (of any kind) to another media or disk.

Job Scheduling: The IT function concerned with ensuring the efficient queuing and processing of data at a predetermined time.

Media: Data storage technologies used to store backed-up data. Media may include floppy disks, magnetic tape, Compact disk (CD), or digital versatile disk (DVD).

Parity: The characteristic of a number in which the sum of the digits is either odd or even. This characteristic is used in error checking in RAID drive configurations.

RAID: An acronym for redundant array of inexpensive (or independent) disks. These disk drives are configured to use two or more drives in combination to improve fault tolerance and performance.

Recovery-Point Objective (RPO): RPO is expressed in terms of how much data the organization can afford to lose if the system fails. For example, if backups were run each night, the recovery point objective would be the end of the previous day's activity. In this case, any data that were entered or processed between the point of failure and the most recent backup would be lost.

Recovery Time Objective (RTO): A measure of how long the organization can effectively function without the computer system.

Striping: A technique for writing data onto multiple disk drives for improved fault tolerance and performance.

Volatility: The rate of change of the values of data in a database or file.

INTRODUCTION

As businesses across all industries grow more dependent on information technology (IT) infrastructure, high availability and backup of IT systems becomes an increasingly strategic business concern. Having the right information at the right time can be the edge to make the difference between profits and losses. But, as the complexity of the IT infrastructure grows, so do the risks. Failures can incur high costs and damage a company's reputation. Especially during unpredictable disruptions or disasters, critical system must be available to prevent the loss of competitive advantages. Therefore, high availability and backup aim at mitigating these risks to ensure continuous availability of critical systems. The mitigation of risks comprises the definition of a business continuity strategy or what traditionally has been referred to as disaster recovery. The business continuity strategy should be aligned with the corporate strategy to allow the optimal consideration of the business requirements. Business requirements generally influence the backup strategy by defining how often specific data must be backed up, how many copies of the data must be retained, or how long different types of data must be stored. The main aim of business continuity is to minimize interruptions of the business processes due to technical difficulties. For achieving these goals, comprehensive planning and commitment of resources are necessary. Typical risks of insufficient business continuity procedures and neglecting the appropriate definition of business requirements include:

- Interruption of critical business processes: Business processes allow the operationalization of the business strategy. Thus, the frictionless execution of business processes is the precondition for generating business value and competitive advantages.
- Loss of corporate data: Often as a result of insufficient security measures or poor IT—or backup—systems the loss of data may result in severe financial or reputational losses and thus in customer dissatisfaction.
- Failure to meet regulatory or legal requirements: Recent corporate financial and reporting scandals (Enron,

WorldCom, ImClone) resulted in new regulations, such as SOX (Sarbanes-Oxley Act, July 30, 2002), HIPAA (Health Insurance Portability and Accountability Act of 1996, Public Law 104-19), or Basel II will require organizations to align their infrastructure with the ability of fulfilling these regulations.

- Failure to meet service-level agreement and recovery time objectives as well as recovery point objectives: This aspect includes backup and recovery guarantees and the definition of times for recovery.

As the saying “all business is local” has been made obsolete by the ongoing revolution in IT, the new challenge facing IT managers is to interconnect previously local networks into one global one. Businesses operating on a global scale no longer have off-hours at night for performing maintenance operations or for restoring backups unnoticed. Online businesses run around-the-clock. Taking all these aspects into account, what are the main concerns for IT managers when dealing with backup systems? Aside from the obvious technical aspects, the focus must be on business requirements such as legal, organizational, enterprise risk management, and security aspects, because these have a strong influence on the definition of backup and restore strategies and the way that storage resources are structured and managed.

OVERVIEW

In this section, we clarify the meaning of certain terms that are related to backups. Figure 1 is a visual overview of all these terms. This initial, simplified overview is meant to foster understanding of the subsequent definitions and explanations. Some of the terms will be covered only in this section. They are mentioned to provide a semantic context for the actual key terms and, consequently, to define the topic of this article. Moreover, the descriptions serve as a starting point for exploring the terms in more detail.

Business Continuity Management

According to the Business Continuity Institute (www.thebci.org), business continuity management (BCM)

Figure 1: Overview of terms

“is a holistic management process that identifies potential impacts that threaten an organization and provides a framework for building resilience and the capability for an effective response that safeguards the interests of its key stakeholders, reputation, brand, and value creating activities. BCM must be owned and fully integrated into the organization as an embedded management process.” In other words, the purpose of BCM is to guarantee that an organization can keep its business going at all times, even in cases of serious disruptions, which means that BCM is about the continuity of business processes. The most important element of BCM is business continuity planning, which is covered briefly in the following section. Management, however, certainly involves more than just planning; the plan must also be executed and involves organizing, leading, coordinating, and controlling.

Risk management is the most important management aspect of BCM. This process begins in the planning phase as risk analysis, and it accompanies every business process through to completion. A short explanation of risk management can be found in the corresponding section below; the interdependence of risk analysis and backups will be covered in more detail in conjunction with the business continuity planning process. One of BCM’s major elements with regard to information systems is the backup process. Later in this chapter we will present a fairly detailed discussion of the backup function from a management point of view. Chapter 175 in this book provides a technical perspective on backups.

A very important distinction must be made between the terms *BCM*, *crisis management*, and *disaster recovery*. The difference lies in the gravity of a given problem. If a business process is affected by a disturbance that was detected in advance and thus earmarked as a potential threat during the risk analysis process of the planning phase, it is regarded as a mere disruption and can be treated and neutralized within the boundaries of the BCM process, since appropriate countermeasures would have been developed and prepared; thus, recovery is relatively easy to achieve. This holds true even in cases in which the disturbance would usually be considered a disaster by common standards.

In contrast, if a business process is affected by a disturbance that was not detected in the course of the risk analysis or, although aware of the threat, no precautions were taken for some reason (e.g., costs), the incident has to be regarded as a disaster for the organization, even if it would not be considered a disaster by common standards. In this case, the required reaction is no longer a matter concerning BCM. Instead, the BCM sphere is exited, and the first step is to conduct crisis management in order to survive the disaster or mitigate its effects. As soon as the situation is stabilized, the disaster recovery procedure is initiated for the purpose of returning to business as usual and moving back into the BCM sphere. These two topics, crisis management and disaster recovery, will be covered briefly at the end of this overview section.

Business Continuity Planning

Business continuity planning (BCP) is a process that intends to set the stage for a reduction of a company’s business risks resulting from disruptions of major IT system functions or operations. As already stated, it is the main element of the BCM process. The BCP process usually consists of the following planning steps, which will be covered in more detail later in this chapter:

1. Initiation
2. Business impact analysis
3. Development of a business continuity plan
4. Training and awareness program
5. Implementing and testing the plan
6. Monitoring and improving procedures

Risk Management

Risk management (RM) is a generic concept that can be applied in quite different contexts, such as, enterprise RM or project RM (see Peltier [2001] for a more detailed description). The basic idea of RM is to deal with the given risks in a planned and controlled manner. Therefore,

a systematic approach should be pursued, which commonly includes the following steps:

1. Establishing the context: This step defines the scope and the focus of RM. These goals should reflect the business requirements for the continuity and information security of the main business functions relevant for information security.
2. Risk identification: This is the process of identifying risks regarding the most critical business processes. Typical reasons for failure include sabotage, terrorism, fire, accidents, IT failure, and power loss.
3. Risk analysis (RA): This is the process determining how often the identified risks occur and estimating the magnitude of their likely consequences.
4. Risk evaluation: This is the process of determining priorities by comparing the identified level of risk against target risk levels or predetermined standards.
5. Risk treatment: According to Peltier (2001) risk can be treated in the following four ways: (a) Risk can be transferred to another party, typically by contracting insurance. (b) Risk can be avoided, which means that the probability that an unwanted incident occurs is systematically reduced. (c) The negative effect of an unwanted incident can be mitigated in advance. (d) The risk can be accepted without special precautions.

Risk analysis will be discussed in more detail in this chapter, as part of the "Business Impact Analysis" phase in the section on "Business Continuity Planning."

Backup

In the context of computer engineering, the term *backup* usually refers to data backup, which means copying data in order to have an additional instance of the original source. Backups are typically stored at a physical distance from operational data to protect them against events that destroy operational data. If the backup is done properly, loss of or damage to the original data can be neutralized or at least mitigated by copying back the data from the backup medium. The latter process is known as data recovery, or data restoring. The data in question can either be data as such (text, image, or audio files, etc.) or stored program code. In both cases, the backup and recovery processes work the same way. The difference between a backup and an archive is that archiving data usually does not involve duplication, whereas backup does.

Of course, the general term *backup* can have a much broader meaning than described above. In all kinds of organizations, it is possible (and reasonable) to back up not only data but also other resources. For example, it is quite common to have backup hardware for critical parts of the system. Likewise, there can be backup provisions for especially important infrastructure elements, such as extra data transmission lines, power supply from an alternate substation, or emergency power supply. Apart from physical backups, it is also wise to define backups of organizational elements. Replacement policies within the staff are fairly common, for instance. Job rotation and

mandatory vacation policies not only help to detect fraud but also enable employees to replace each other. It is also conceivable to set up alternative processes for certain essential business functions in order to compensate for a temporary failure of the primary processes caused by extraordinary external influences. In the case of a rather unstable procurement situation, the availability of proper backup providers for important externally purchased services must be granted.

However, in most cases *backup* refers to data backup, whereas its wider meaning is covered by the expressions "business continuity management" and "business continuity planning." Because *backup* refers to data backup in this chapter, the rest of this section will give an overview of the characteristics of data backup (for further reading see Bishop [2002]).

Guidelines for Backup

A thoroughly established backup strategy is more than just arbitrarily copying data from time to time. It takes careful planning and adherence to certain guidelines focusing on the following aspects:

- The responsibility to perform backups must be clearly assigned by defining an organizational role.
- Backups must be carried out on a regular basis. To fulfill this requirement, backups should be automated (e.g., within a networked storage infrastructure) in order to require only minimal human intervention. Storage area networks (SANs) are replacing direct attached storage (DAS) because they allow the centralization of the storage systems and provide a higher security level. Furthermore, the regular verification of the backups must be ensured.
- The backup medium should be kept at a different location from the original data. This secondary location should be as safe and as secure as the primary location. If removable media are used for backups, the availability of the corresponding drives has to be guaranteed. Therefore, data backup may demand hardware backup as well.
- Backup media have to be tested at regular intervals to ensure that they are still readable. When the life cycle of the technology used is about to reach its end, the data should be transferred to a different medium. Further note that backups should use well-established standard formats.
- The users of the system should be made aware of all relevant parameters of the backup process. In particular, they should know how to request the recovery of lost data.

Apart from these minimum requirements, there are also other guidelines that should be followed to further improve the quality of the backup function. These measures might cause higher initial costs, but most could save a lot of time and money in the case of a more serious disruption:

- The procedure of performing a backup should be defined as simply as possible.

- Carrying out a backup run should be possible without interrupting normal day-to-day business.
- For each piece of data, at least two copies should be made. These copies should be stored on different media and kept at different locations. An effective backup rotation scheme should be applied, which means keeping backup images of several points in time of the recent past and gradually fewer of the older states.
- The backup should have a certain degree of deliberate redundancy, such as checksums or hashes, in order to facilitate the validation of the copy's integrity without needing the original data.
- Different kinds of data usually have different update frequencies and should consequently have different backup frequencies as well. If a backup is distributed over multiple volumes, recovery should not need all volumes to be readable or present.

Data Recovery

The term *data recovery* refers to the process of restoring data from a backup medium in case the original source of data has been damaged or destroyed. Data recovery is not the same as data salvaging. The latter refers to the process of rescuing data directly from a damaged or destroyed storage medium. Every backup without an appropriate recovery strategy is practically useless. For example, if the software that is needed to read and restore the backup data is destroyed along with the original data, the copy is rendered worthless.

In principle, there are two scenarios in which data recovery might be necessary. First, in the more grave one, a complete data carrier, or a considerable part of it, is damaged or destroyed. Here, the backup usually has to be restored in order to bring the system back to an operational state. Examples would be the loss of a hard disk or the file system getting corrupted so badly it can no longer be read. The second scenario, which is sometimes overlooked, although it is more common, is the need to recover a single file, directory or data set, lost by accidental deletion or corrupted by a program.

Scope for Decisions

In contrast to the guidelines above, which we suggest applying in all cases, there are some important decisions about backup for which no general recommendations can be made. They simply depend on the situation and various environmental parameters. Two of the most relevant aspects involving more than cost alone will be presented in this section. The first is which type of media to use as backup data carrier. The possibilities are subject to change over time. In the late 1980s and the 1990s, floppy disks and magnetic tape were common. Nowadays, hard disks and optical disks serve as backup media. In areas (e.g. the health sector, digital libraries) for which terabytes and even petabytes must be saved, newer generations of tapes (such as digital linear tape [DLT] and linear tape-open [LTO]) are still one of the most reliable solutions. With widespread broadband network access, a new trend emerges: remote backup, also referred to as online backup or Internet-based backup. In this case, the customer of the backup

service does not know the actual type of storage media used.

The most appropriate medium depends on certain criteria. First of all, the price per gigabyte is a crucial aspect. Second, the specific technical properties of the medium, such as speed, reliability, and ease of use must be considered. In the past a considerable disadvantage of magnetic tape was that it could be read only sequentially. Nowadays magnetic tape provides structures that allow fast recovery of single files. Also of particular relevance is whether a medium can be written on only once or many times. The advantage of a rewritable data carrier is that it can be reused, which saves costs and facilitates the implementation of a proper rotation scheme. On the other hand, a write-once medium is better from a security perspective or when revision-proof archiving is needed, as the data cannot be manipulated later. Third, durability is an important issue, because with new storage technologies one has to be aware that the life expectancy of the medium can only be estimated and is far from certain. Conventional magneto-optical WORM (write-once, read-many) disks guarantee readability for up to 40 years, but they are slow compared with magnetic tapes and several times more expensive. As previously stated, backups must be recopied to new types of storage media to avoid obsolete technology.

Another important decision concerns whether or not to compress backup data. From the technical point of view it would be better not to compress the data, as uncompressed data can be recovered more easily in case of damage or corruption of the backup media. Considering the cost aspect and the increasing data volume, on the other hand, compression makes sense. Still, this decision is not just a matter of cost. It should be considered in connection with the possible encryption of the backup data for security reasons, as this would also be some kind of manipulation to the data. So, if the data need to be encrypted, it can also be compressed since today's block ciphers usually operate in cipher block chaining (CBC) mode. The encryption of sensitive data should be an integral part of the security strategy, because the backup tape is a mirror of the server's contents. The chronological order of encrypting and compressing is important, as compression algorithms are not working effectively on encrypted data. In addition, key management should match the corporate business processes—for example, to grant that the keys expire when data expire. However, the total cost of encryption must be compared to potential risks and the likelihood of a security breach to determine the cost-benefit ratio of encrypting backups. In addition, decision makers have to consider that it can take longer to complete an encrypted backup than a comparable nonencrypted backup. The time needed for encryption depends on the type of data, the encryption algorithms, and the type of encryption software or hardware as well as the underlying infrastructure such as disks, tapes, or processors. Today, many vendors of tape backups provide built-in encryption capabilities in their products. This solution has additional overhead, and key management is very basic. The latest storage encryption methods use hardware-accelerated appliances that are located in the SAN. They offer very good performance but have higher costs than other solutions.

The secret keys of the appliances can be stored on a set of smartcards that can be distributed to selected people. Encrypted data can be deleted by destroying selected encryption keys.

Best Practices for High Availability

Along with the gradually expanding availability requirements of today's businesses, making backups is increasingly tricky. It is obvious that any kind of maintenance work, including backup, can be performed more easily if the corresponding business process is regularly halted for a certain amount of time, such as over the weekend. With the need for 24/7 availability, this so-called batch or backup window is no longer available. However, there are some techniques that help in carrying out backups even within a very small or (for the system as a whole) practically nonexistent time frame:

- *Partitioning* the source data, for example a large database, makes it possible to back up only a small part, an individual partition, of the source data at a time, thus providing increased operational flexibility.
- *Incremental backup* is a technique in which only changes of the data via a certain base copy, the so-called deltas, are stored. Consequently, the elapsed time to complete a backup or recovery operation can be reduced in comparison to full backup.
- *Parallel processing* is a divide-and-conquer approach, in which backup is performed for multiple partitions of the source data at the same time. Naturally, for this technique, multiple data carriers need to be available in parallel, which usually means multiple drives of some kind. The advantage of parallel processing is an increased bandwidth of the backup (and restore) activity.
- *Concurrent backup* is a technology offered by most database vendors that allows backup even of data structures that are still online and in use. Consequently, no

business process has to be interrupted, which leads to extended availability.

BUSINESS CONTINUITY PLANNING

This section describes the steps of the BCP process in detail (see Figure 2) and focuses on the business impact analysis as the most important element of the BCP process. Although the last three steps of the process are to be executed after the plan has been developed, their realization still needs to be planned beforehand, which is why they are covered as part of the planning process. Analyzing business processes and the impact of nonavailable data is of paramount importance to implement a backup scheme that efficiently supports business objectives.

Initiation

First, the BCP project has to be initiated. Although it might appear somewhat trivial at first, this phase is very important. The following points must be considered when launching the project:

- Support and involvement of the organization's senior management and board have to be obtained and confirmed.
- Senior staff support, especially from key business and technical stakeholders, has to be obtained and confirmed.
- The BCP project team has to be formed. There should be representatives from all critical business functions, such as human resources, accounting, IT, etc.
- Objectives and constraints of the project need to be defined and transformed into a roadmap with strategic milestones.
- A draft version of the overall business continuity policy has to be defined and communicated to the project staff.

Figure 2: Business continuity planning life cycle

Business Impact Analysis

Business impact analysis (BIA) comprises the assessment of each of the business requirements and their ranking according to their importance to the company. A typical business impact analysis will consist of the steps defined in the following sections. The BIA measures the severity of the impact on the company according to multiple objectives such as operating costs, regulatory fines, and financial losses or loss of reputation if certain business functions become unavailable.

Prior to implementing any backup solution, to ensure continuity a business case study must be made. Since simply backing up data cannot guarantee recovery of critical data, many additional measures have to be considered, such as testing of backups, establishing alternative processing sites, and security policies for offsite storage of backups. Moreover, one has to make sure that only truly necessary data are backed up. Storing and recovering unnecessary data adds additional costs and time for recovery.

Business Process Analysis

In this step, all business processes must be identified and then ranked according to how critical they are. Knowing how crucial processes are is important for determining the most appropriate backup scenario. For accurately categorizing the business processes the following questions should be considered:

- Are the processes main contributors to revenue?
- What is the relationship between length of interruption of processes and consequences (loss of customers, loss of revenue, loss of reputation)?
- Do the processes deal with sensitive data?

- Are the processes related to safety or health of people (nuclear power plant maintenance, traffic control systems)?
- Which legal requirements (SAS 70 [Statement on Auditing Standards No. 70: Service Organizations], SOX) must be considered?

IT Infrastructure Mapping

In the penultimate step, the relationship between business processes and IT infrastructure must be established. Therefore the following question must be considered:

- Which systems are necessary to execute certain core processes?
- Which systems can go offline without interrupting normal business process operations?

This is the most important and most underappreciated step. In many cases, system functions that are not deemed critical may still have a negative influence on critical systems in cases of system interruption. The most appropriate safeguard to alleviate this is an identical test system, which can be used to simulate various failures. Still, most test systems—especially in smaller companies—are not completely identical, because of cost restrictions. Therefore, the analysis of system interdependencies is crucial to ensure that business continuity scenarios are consistent with reality. The identified systems may be classified using the following framework shown in Table 1.

Risk Analysis

In companies that depend heavily on IT systems, attaining security attributes (confidentiality, integrity, and availability) is a major goal of management. For example,

Table 1: Analysis of System Interdependencies

Classification	Description
Nonsensitive	Even when interrupted for a prolonged time span or when done manually, the business impact is minimal. Resuming requires little or no catching up. <i>Examples:</i> very small companies, typical office application that can easily be relocated to other workstations
Sensitive	These functions can be done manually and for an extended period, though at considerably higher costs than normal operations. Additional staff may be required. <i>Examples:</i> mass mailings, computer-supported accounting for smaller companies
Vital	For a brief period, these services can be done manually. Usually, if operations are restored within a timeframe of up to 7 days, the costs are still within reasonable limits and much lower than for critical systems. <i>Examples:</i> access to central file servers, e-mail, or other resources
Critical	These services cannot be done manually and require virtually identical infrastructure capabilities. Tolerance to interruptions is low, cost of interruption is high. <i>Examples:</i> accounting systems of financial institutions, databases or Web servers of large Web stores

a hacker who attacks and crashes a server reduces the availability of this server. If there is no appropriate recovery procedure, the server crash will have a major impact on the department's or even the entire company's efficiency. The loss caused by the resulting failure of a business process that requires the crashed server will affect the decision whether to buy a backup system or to implement mirror processing at a remote site. However, if the server is used for noncritical tasks and the business process can also be performed manually at a tolerable cost, expensive recovery mechanisms make little sense. In this case, the cost of implementing a backup system may exceed the potential benefits resulting from minimizing loss.

Therefore, the process of risk analysis must focus on identifying risks that negatively affect the execution of critical and strategic business processes. A company must develop a clear understanding of potential threats causing business process interruptions and their ramifications. Risks need to be sorted by impact and likelihood, and must also be categorized (see Neubauer, Stummer, and Weippl [2006] for a description of workshop-based risk analysis). The following risk categories must be considered in the process of risk analysis (Peltier 2001):

- **External factors:** The interactions with clients, business partners, and environment are referred to as external factors. This also includes criminal activities—for example, by hackers—as well as services and deliveries provided by external partners.
- **People:** The entire staff—from top management to the operational level—that are needed for the execution of the corporate business processes.
- **Systems:** This area comprises the entire technical infrastructure—with a special focus on IT and telecommunications—needed for the optimal execution of the critical business processes.

There are various approaches for efficiently performing a risk analysis. Basically, all of these approaches can be divided into qualitative and quantitative approaches.

Qualitative Risk Analysis

Qualitative risk analysis uses relative values for evaluating potential threats. Methods such as questionnaires, checklists, and workshops with experts from different departments of the organization are commonly used. Therefore, this method strongly relies on people's experience, opinions, and intuitions. The advantage of qualitative risk analysis is that it is easier to reach consensus as compared with quantitative methods. Thus, results are available sooner and at lower cost. The drawback of qualitative methods is that the relative values are not applicable for (for example) conducting an accurate cost-benefit analysis. Commonly used techniques are the following:

The Delphi technique—The Delphi technique (Gupta and Clarke 1996) is used for eliciting information and judgments from a small group of participants and achieving consensus among these experts. This method is often used when there are insufficient or unreliable

data. The objective of this method is to isolate the inputs of each expert to prevent the influence of rank or of strong personalities. Therefore, there is no direct communication between the team members, and the participants do not sit together in a meeting. Instead, information is exchanged via mail, fax, or e-mail. The facilitator coordinates the whole process and provides support to the team members. The facilitator defines the issue and prepares and sends the first questionnaire to the participants. Each participant returns his or her ideas and thoughts to the facilitator, who compiles the ideas and sends a second questionnaire. The process continues until no new ideas emerge and all strengths, weaknesses, and opinions have been identified and discussed.

Risk (rating) matrix—The risk matrix is a table that shows the relationship between likelihood, impact, and level of risk. As stated before, the level of risk comprises the combination of the impact and the likelihood of the threat occurring. The matrix contains a description of the risk, a unique ID for each risk, a likelihood of occurrence, an impact, and the risk that is the product of likelihood and impact. Therefore, levels of risk can be determined by using a risk matrix. To categorize likelihood, impact, and levels of risk, the National Institute of Standards and Technology (NIST) uses three terms (low, medium, and high). NZ(AS/NZS 4360, 1999, 2004) uses five levels of categorizing likelihood (almost certain, likely, possible, unlikely, and rare/almost never), five levels of impact (catastrophic, major, severe, moderate, and minor), and four levels of risk (low, medium, high, and critical). The risk levels are prioritized in order of magnitude from low to high.

Threat Trees

Threat (or attack) trees (see Figure 3) provide a formal, methodical way of describing the security of systems, based on different attacks (Schneier 2000); the potential threats to a system are described in a tree structure. The root node of the tree shows the goal of the attack, whereas leaves describe different ways of achieving the goal. These nodes can be defined as OR nodes for describing alternatives or AND nodes for representing a state in which it is necessary to fulfill more than one subgoal in order to achieve the goal. An attack path is a route from a leaf to the root, taking AND nodes (and their subtrees) into account (Swiderski and Snyder 2004).

Quantitative Risk Analysis. The goal of quantitative approaches is to calculate numeric values for all assets and potential threats. Therefore, two fundamental key figures are used: First, the *probability* of the occurrence of an event and, second, the *impact* of its occurrence.

For all identified threats, corporate decision makers have to assign reasonable values to both categories. Moreover, they have to value the assets at risk. There are many ways to estimate the value of an asset, such as profit loss due to lost productivity or reputation, or cost to recover. The drawbacks of this approach are, on the one hand, that the so-called accuracy of the calculation hides the fact that the numbers are based solely on imprecise estimates.

Figure 3: Example of an attack tree (Schneier 2000)

To partly overcome this weakness, historical data can be used, if available. On the other hand, the use of quantitative approaches can be very costly, involve many stakeholders, and take a long time. Nevertheless, the use of concrete numbers allows the objective comparison of results, and thus serves as a basis for a cost-benefit analysis. Quantitative risk analysis is essential for decision making and must be based on financial figures. Examples for methods of quantitative risk analysis are the following:

Annual loss expectancy—Annual loss expectancy (ALE) (Federal Information Processing Standard 1979) is a method for calculating a company's potential losses caused by security breaches. Loss values are compared to the investments needed for their mitigation. ALE is calculated by multiplying the expected loss of an event with its rate of occurrence. The single loss expectancy (SLE) is the monetary value that is lost if the risk occurs once. This value includes the costs for fixing or replacing the asset, and, in addition, the wages for the person fixing the problem and for the employees who are unable to work during this time. Beside the impact of a security breach, the likelihood of a risk occurring within a year—the annualized rate of occurrence (ARO)—must be determined.

For example, a Web server hosting an e-commerce site that generates revenue of \$ 20,000/hour is down for 3 hours because of an attack by a hacker. (We assume that buyers do not return for the intended purchase if the site is not available, and that their choice of where to shop the next time is not influenced.) We assume that the rate of such an event is 0.5 (i.e., once in 2 years) and the costs for replacing the server are \$5,000. So,

the SLE of the risk is \$65,000. ALE is calculated using this formula: $ALE = SLE \times ARO$. Thus, the ALE for the example with the Web server would be \$32,500. Based on this value, decision makers can determine whether it is beneficial in terms of monetary value to purchase (for example) a firewall for protecting the Web server.

Extended ALE approaches—In addition to the typical problems of quantitative approaches, a major drawback of ALE is its combination of impact and rate of occurrence into a single number. That makes it impossible to distinguish between events with high frequency and low impact and events with low frequency and high impact. Hoo (2000) uses an approach based on ALE to calculate the benefits of additional investments in security safeguards.

Multiobjective portfolio selection—Traditionally, security safeguards are evaluated through a single (aggregated) criterion, such as return on investment. These approaches may no longer be sufficient as economic and legal requirements force top management to consider security issues in a more differentiated way. Most real-life issues have multiple risks and uncertainties; multiple objectives need to be achieved, although they are often mutually exclusive, such as minimizing costs while enhancing protection. In addition, different and changing preferences of several stakeholders must be taken into account. Existing approaches stem from Guan et al. (2003), who apply methods from multicriteria decision support to risk management. Gupta and Clarke (1996) propose a decision-support approach based on a genetic algorithm for security portfolio selection; Strauss and Stummer (2002) introduce a

Figure 4: Multistep approach to addressing risks

two-step interactive multiobjective decision support approach for selecting portfolios of measures in IT risk management. Their approach interactively assists IT managers in reducing a given risk by evaluating and selecting pareto-optimal (an allocation in which there is no feasible reallocation that would be strictly preferred by all agents [http://en.wikipedia.org/wiki/Pareto_efficiency]) portfolios of security measures. This approach is extended in Neubauer et al. (2006) by defining a workshop environment for the multiobjective selection of security safeguards.

Risk Evaluation

Once all risks have been identified, they need to be addressed in a step-by-step process. Figure 4 shows an iterative approach for addressing risks that comprise the following steps:

1. **Scope definition:** First, the scope of the risk analysis must be established. Some major catastrophic events, such as nuclear fallout or a hit from a meteor, might be considered out of scope and therefore discarded.
2. **Identification:** In the next step, a list of potential risks is created. Popular methods are questionnaires, interviews, and workshops.
3. **Avoidance:** Some risks might simply be avoided. This might reduce or limit business to a certain degree, but usually does not generate any additional costs.
4. **Reducing frequency:** In IT, reducing the frequency of major risks usually implies improving the hardware equipment by investing in redundancy or high-availability (HA) systems.
5. **Reducing impact:** In the case of business continuity planning, backup procedures are the most common way to reduce the impact of all kinds of risks resulting in data loss.
6. **Transferring risks:** Typically, risks that cannot be avoided or reduced are mitigated by contracting the appropriate insurance.

7. **Accepting risks:** In some cases, all available options to avoid, reduce, or mitigate a risk might be unacceptably expensive. In these cases, the risks are accepted, though not covered.

Development of a Business Continuity Plan

By correlating the business requirements with the current IT infrastructure and combining it with the results of the risk analysis, a first outline of the business continuity plan becomes apparent. The plan has to be elaborated in more detail by developing policies and procedures for each of the critical business functions. In the first step, the preferred business continuity service levels must be defined for every important business process. This measure includes establishing profiles for continuity and recovery. The recovery objectives must be quantified in terms of recovery time objectives (RTOs) and recovery point objectives (RPOs). RTOs define the time it takes to restore the business function to an operational level. RPOs define the specific point in time to which the data need to be restored in order to effect a successful recovery. A more detailed discussion of recovery objectives can be found below.

The second step includes the development of possible continuity approaches for each threat, according to the continuity service levels set before. The threats are those that have been identified in the course of the business impact analysis. Now, the available approaches must be evaluated in terms of time, cost, and benefits. After the best approach for each threat has been determined, corresponding continuity procedures can be worked out in detail. In principle, the plan comprises the entire collection of policies and procedures.

Recovery Objectives

A major step when designing and implementing backup systems is the identification of various recovery strategies and available alternatives for recovering from an

interruption. The selection of the appropriate strategy is based on the business impact analysis and criticality analysis. There are two metrics that help identify and determine the recovery strategies; the recovery point objective (RPO) and the recovery time objective (RTO). The RPO is determined based on the acceptable data loss in case of disruption of operations. It indicates the earliest point in time at which it is acceptable to recover the data. For example, if losing the data up to 12 hours prior to the disruption can be afforded, then a backup no older than 12 hours must be available. The transactions between the RPO and the interruption need to be entered manually after recovery or may be omitted entirely. Moreover, the RPO clearly quantifies the amount of accepted data loss in case of interruption.

Unlike RPO, the RTO is based on the acceptable down time in case of a disruption of operations. This value indicates the latest point in time at which the business operations must be resumed after an interruption. However, both metrics are based on time parameters. The lower the time requirements, the higher the cost of recovery strategies; for example, if the RPO is a matter of minutes, then data mirroring or duplexing should be implemented as the recovery strategy. If the RTO is less, then an alternative site might be preferred over a hot site¹ contract. The lower the RTO, the lower the interruption tolerance. Interruption tolerance is the time gap within which the business can accept nonavailability of IT facilities.

In order to ensure an effective recovery, a recovery strategy should be established by the organization. A recovery strategy combines preventive, detective, and corrective measures. The main actions are as follows:

- Remove all possible threats
- Minimize the likelihood of occurrence
- Minimize the effect of occurrence

Removing threats and minimizing the risk of occurrence can be addressed through implementing physical and environmental security measures. Minimizing the effect can be achieved by implementing built-in resilience through alternative routing and redundancy. In the first step of creating a recovery strategy, prospective resilience mechanisms should be evaluated by taking built-in solutions into account. The future disruption recovery procedure will address the restoration of affected facilities that are obviously not covered by resilience concepts but are identified as significant for business functionality by senior management.

The recovery strategy identifies and describes the best ways to recover a system in case of interruption or failure. It

can be seen as a guidance document that includes detailed recovery procedures that can be used in different strategies, including alternatives. The alternatives should be documented and presented to senior management. Finally, it is a management responsibility to identify the most appropriate strategy from the alternatives provided. The selected strategy should be used to further develop the detailed business continuity plan. When senior management decides which alternative to identify, the selection of the strategy depends on the following four criteria:

- Criticality of the business process and the corresponding application
- Cost of the recovery solution
- Time required to recover the service
- Security considerations when compromising the established security architecture by implementing new systems

Of course, there will be various strategies for recovering critical information resources. However, the appropriate strategy is the one with a reasonable cost for an acceptable recovery time as compared with the impact and the likelihood of occurrence as determined in the business impact analysis. The cost factors also have an impact on senior management's decision. The cost of recovery is the cost of preparing for possible disruptions (e.g., purchasing, maintaining, and testing all duplicate and redundant facilities and systems), as well as the cost of putting these into use in the event of a disruption. The latter costs can often be insured against, but the former generally cannot. The premiums for disaster insurance will usually be lower for an organization with an appropriate plan.

Every platform that runs and supports a business-critical application (i.e., one that is required for a critical business process or function) will need a documented and approved recovery strategy. Strategies would need to be developed for facilities such as the following:

- Hot site
- Warm site
- Cold site
- Duplicate site
- Mobile site

Training and Awareness Program

In order for a business continuity plan (BC plan) to work effectively in an organization, staff must receive the appropriate instructions. Consequently, thoroughly planning and realizing a training and awareness program for business continuity is an imperative step in the process. However, the inspiration of a continuity culture within the organization is not without obstacles, as organizational priorities of day-to-day business usually appear more important to the employees. It is therefore fairly difficult to maintain a high level of awareness if no major business disruptions occur. Therefore, BCP exercises need to be conducted on a regular basis in order to establish this issue as a high organizational priority. Another means to

¹"A hot site is a commercial disaster recovery service that allows a business to continue computer and network operations in the event of a computer or equipment disaster. For example, if an enterprise's data processing center becomes inoperable, that enterprise can move all data processing operations to a hot site. A hot site has all the equipment needed for the enterprise to continue operation, including office space and furniture, telephone jacks, and computer equipment." Verbatim quote from http://searchcio.techtarget.com/sDefinition/0,290660,sid19_gci557324,00.html.

raise awareness is the frequent involvement of employees in periodic review and evaluation of the policies and procedures of the BC plan. One might even try to inspire people to transfer the basic ideas of BCP to their personal lives, thus stimulating intrinsic interest in the subject.

Implementing and Testing the Plan

Unlike newly developed software, in the case of BCP, it is not feasible to set up a complete test environment, as this would mean duplicating the entire organization. Therefore, before testing, the plan needs to be implemented, at least in some small sector of the organization. The easiest way to implement the plan, from the point of view of the BCP responsible, is to distribute the BC plan to all department managers and then hold them responsible for its realization in their particular areas of competence. Of course, proper support must be provided along with this measure.

After implementation, the plan must be tested. Since acceptance criteria are basically defined by the required service levels of the BC plan, formulation of a matching test schedule with major testing milestones is all that is necessary. Basically, testing the BC plan involves simulating possible disruptions and documenting the results of the corresponding continuity measures. Finally, the test run has to be evaluated; this is the next step in the process.

Monitoring and Improving the Procedures

Every plan should be reviewed from time to time. Naturally, the same is true for a BC plan. The first occasion for reviewing the BC plan is the initial test run. Depending on the acquired results, necessary improvements to the plan should be carried out and communicated to the employees. After this first review, an iterative monitoring-and-improving cycle must be set up as a permanent facility. This way, changes in the contexts or properties of the critical business processes, which can very well be anticipated in today's dynamic world, can be detected in due time, making it possible to formulate appropriate changes to the BC plan before a disruption. In addition, there are certain occasions when special reviews of the plan are highly recommended: following a BCP exercise by the regular staff training program and, even more, after a real disruption or disaster.

CONCLUSION

The general public may see backup of data as the solution to availability requirements. There is, however, no business requirement for backups—it is the successful recovery of business-relevant data after disruptions that should interest management. Preparing for complex recovery procedures adds considerable costs to the operation of the IT infrastructure. It is therefore essential to apply due diligence in the planning process in order to identify critical data and critical systems, as well as to estimate acceptable RPOs and RTOs. The planning has to start with the business strategy that serves as the basis for defining the business requirements of the backup strategy. For

defining business requirements decision makers have to focus on business processes, regulatory and legal requirements, or service-level agreements. This chapter defines the major parts of business continuity management and describes the process of business continuity planning as an integral part of business continuity management in detail.

GLOSSARY

Business Continuity Management (BCM): The purpose of BCM is to guarantee that an organization can keep its business going even in cases of serious disruptions.

Business Continuity Planning (BCP): BCP is a process that intends to set the stage for lowering a company's business risks resulting from disruptions of major IT system functions or operations. It is the main element of the BCM process.

Risk Management (RM): The most important management aspect of BCM is risk management. The basic idea of RM is to deal with the given risks in a planned and controlled manner.

Recovery Point Objective (RPO): The earliest point in time at which it is acceptable to recover the data.

Recovery Time Objective (RTO): This value indicates the latest point in time at which the business operations must be resumed after an interruption.

INTRODUCTION

As technology advances, some improvements provide a greater positive impact than do others. The improvements in electronic storage media, such as magnetic tape, hard disks, and flash drives are allowing organizations to be more flexible in choosing the media for various applications such as daily backups, disaster recovery, and long-term data archiving. This chapter discusses the issues that are important to consider when evaluating media options for electronic data storage. While capacity (the amount of data that a particular medium will hold) is usually the first consideration, other factors—such as longevity, reusability, and cost—should also be determined before making a choice. Evaluating each of the characteristics discussed in this chapter with organizational goals in mind will help in selecting the optimal medium for any application.

SELECTION ISSUES

Longevity

When selecting media for storing electronic data, one of the important considerations is determining how long the media will be viable. Certain storage media, such as magnetic tape, are frequently warranted for 10 years or longer, but usage factors—including frequency of use, storage conditions, and condition of the drive in which the tape is used—can dramatically alter the usable life of individual tapes. The same caution is true for other media. In most cases, the longevity of the medium is related to the conditions in which it is used and stored.

Longevity should be viewed in the long term for archival purposes, and in the short term for backup purposes. If the purpose of storing data is to maintain a long-term archive so that the data may be (accessed years after it was initially created, then the user should consider the likelihood that the technology used to read and write the media will be available years in the future. In long-term

data archives, the drives used to record data may become obsolete before the physical deterioration of the storage media (Brown 2003).

If the purpose of storing data is to mitigate the risk of data loss due to system failure, as in the case of periodic backups, more consideration should be given to usage issues such as whether the medium is reusable or prone to physical damage or failure as a result of environmental conditions. Media life may be extended by adopting techniques that prescribe frequent media rotation. For example, rotating through a set of five daily backup tapes (one for each business day) would extend the usable life of each tape over rotating through three backup tapes. During a normal month, a single tape would be used four times as part of a five-tape set versus seven times as part of a three-tape set.

When comparing longevity among various technologies, it is important to note the rate of improvement for every aspect of technology. As with all the characteristics described in this chapter, comparisons among different options should be viewed as relative to one another and not absolute. Kryder's law states that hard disk drives are improving in the density of information at an exponential rate (Walter 2005). Although this phenomenon is not consistent among all types of storage, it demonstrates the rapid pace of change in storage technology. Comparisons of various storage characteristics in this chapter represent the relative capabilities of different media options, and will likely change as technology improves. The comparisons are presented (in as up-to-date terms as possible) so that the user can identify key benchmarks for various media choices.

Capacity

The amount of data that can be stored on a particular device such as a disk or tape defines its capacity. When choosing the media for backups or archives, fewer media

Table 1: Removable Media Capacity

Media	Estimated Capacity
Floppy disk	1.44 Mb
Removable disk	100 Mb to 35 Gb
Compact disk (CD)	184 to 870 Mb
Digital video disk (DVD)	1.46 to 4.7 Gb (per side)
Magnetic tape	20 to 800+ Gb
USB flash drive	128 Mb to 64 Gb

per session is more efficient. Table 1 shows some relative capacities for removable media that could potentially be used for backups.

The capacity of a removable medium is more important when a backup of large amounts of data is necessary. If the amount of data being backed up exceeds the capacity of a single medium, then multiple media sets (i.e., two or more tapes) must be used. This requires human intervention to remove one medium and insert subsequent media, or the use of an automated loader. Automatic tape loaders are readily available and widely used for managing large backup jobs. A drawback to using an automated loader is that the device adds a level of complexity to the process and provides another risk of failure to the backup and recovery system.

Data Growth

A careful assessment of capacity needs should include an analysis of the growth rate for data created by the organization. Some obvious areas in which the amount of data increases consistently may include transactional databases or operational data. Growth in other areas, such as e-mail and e-commerce data, may outpace these traditional data sources. Growth in the context of media capacity may be defined as the increase in capacity required to store electronic data. As more data are entered, generated, or acquired by the system, more storage capacity is required. The storage requirements for e-mail and e-commerce applications generally increase at a faster pace than that of some other applications (Lee 2002). When determining the most effective medium for archiving data, growth is an important consideration. Ignoring the increase in data over time could lead to excessive wear on removable media, added complexity in managing and storing media, and loss of efficiency in backup operations.

Data Transfer Rate

The transfer rate refers to the amount of data that can be transferred from one location (usually the primary medium, such as a hard drive) to another location (usually a secondary medium such as tape) in a given period of time. Some estimates for data transfer rates for tape drives range from below 10 Gb/hour up to over 300 Gb/hour. The transfer rate of the device used for backups and archiving is important, because with a fast transfer rate, the

backup can be completed in less time, and the system will return to full operation sooner. For example, if the size of the data set to be backed up is 100 Gb and the tape drive is able to transfer the data at 300 gigabits per hour (Gbp/h), then the backup can be completed in 20 minutes. If the tape drive is slower, and can transfer data at only 10 Gbp/h the same data set would require 10 hours to back up. Another issue that should be considered is how fast the data can be supplied to the backup device. If the data are being backed up via a 10BaseT Ethernet network, then the maximum throughput could not exceed 10 megabits per second (Mbps). In this application, using a tape drive that is capable of a 30-Mbps transfer rate would not be supplied with data at a rate fast enough to run continuously. The drive may start the tape, empty its buffer (to the tape), then stop the tape while waiting for more data from the Ethernet network. This start-stop-start action would significantly reduce the life span and reliability of the tapes (Yamagaki, Tode, and Murakami 2005). Transfer rates that could “starve” the device are not generally a problem for nontape media. Optical media such as CDs or DVDs can buffer the data, and not experience significant problems when transfer capacity exceeds the system’s ability to supply data.

Integrity

Data integrity implies that the data stored on a particular medium is correct. When data are corrupted during transfer from one storage medium to another, an integrity violation occurs. Integrity violations can occur because of hardware malfunction, software errors, or physical media problems. Methods used to reduce the risk of integrity violations include checksumming, cyclical redundancy checks, and error correction code (Sivathanu, Wright, and Zadok 2005). Most backup and archival software provides features to test media immediately after a backup using one or more of these techniques. If an error is detected, then the data is rewritten and tested again, or a message is generated to inform the user of the error. Testing the medium after a backup process is sometimes optional, and adds additional time to the overall backup process, but skipping the verification step adds to the potential risk of having an unusable backup medium.

Reliability

This chapter is concerned primarily with media, but most media are closely tied to the drive from which the media are read and written. Tape and disk drives vary in their ability to operate effectively over time. To quantify this ability, manufacturers have developed two measures of product reliability. The first is mean-time-between-failures (MTBF). This is a number, frequently expressed in hours, that indicates the average time that a drive will operate without failing. The second measure, the annualized failure rate (AFR) is a measure of the probable percentage of failures per year when compared to the total number of installed drives of the same type and same manufacturer.

It is important to identify the duty cycle for any reliability measure. The *duty cycle* generally describes how much of the time a drive operates during a given period.

If a tape drive were used only for backups, which take 2 hours per day, then the duty cycle would be about 8 percent. When describing various drives, manufacturer's claims of reliability should be examined to determine the duty cycle of the product. Manufacturers' MTBF claims can range from a 10 percent to a 100 percent duty cycle.

Other factors that may affect reliability include operating conditions such as temperature and humidity, frequency of cleaning the drive (in the case of tape drives), and the quality of the medium used in the drive (De Graaf 2001).

Obsolescence

Media used for data storage and its supporting hardware should be based on mature technology. Mature technology is more likely to be supported by open standards, multiple vendors, and a sustainable marketplace for support and supplies (Brown 2003). As changes in technology occur, some methods and products will experience brief success then vanish from the market. It is important to attempt to quantify the lifespan of the media and drive technology under consideration before adopting any specific solution. In many cases the drive technology will become obsolete before the media itself becomes unusable. In his article titled "The Digital Dark Age," John Huxley (2005) describes a scenario in which 50 years in the future, two children discover a CD-ROM along with a letter explaining the data it contains. The children have never seen a CD-ROM and have no way of retrieving the data. Although a 50-year window may be a long time for backups or most archival purposes, the scenario may prompt one to consider what the realistic operational life span may be for the technology used to preserve company data. Another way to gain perspective on the potential problem of obsolescence is to try to find a computer that will allow you to retrieve data from a 5.25-inch floppy disk or listen to your favorite 8-track audio tape.

Cost

The total cost of ownership (TCO) for various media must be calculated for several potential areas. The first is the medium itself. Media costs include media that will be used in a rotational scheme, such as daily backups, and media that will be used for archival purposes, such as monthly, quarterly, or annual backups. Purchasing media in bulk quantities may provide some cost savings. The potential for damaged media (i.e., broken tapes or scratched CDs) should be considered, so that enough media are on hand to perform the required tasks.

Another cost associated with media is the hardware or device used to access it. Hardware costs for various drives should include the cost of the device and the cost of maintenance for the device. Maintenance should take into account supplies such as cleaning kits or cartridges and contracts for repair. Any special software used in backups and archiving should be evaluated, along with software maintenance fees.

Media must be stored in a climatically controlled environment to continue to be viable over time. Climatically controlled floor space costs should be determined and

Table 2: Media Cost Comparison

Cost Factor	4 mm Tape Cartridge	CD-ROM
Media cost/year	\$289.00	\$236.00
Hardware	800.00	300.00
Hardware maintenance	180.00	65.00
Software	625.00	425.00
Software maintenance	50.00	30.00
Floor space cost/year	680.00	600.00
Operational costs/year	800.00	1030.00
Total	\$3424.00	\$2686.00

the amount of space required should be part of the cost of choosing a given medium. Options such as robotic tape-manipulation devices, which maintain large tape libraries with near-online access require much more floor space than optical disk technologies. These costs may be significant or insignificant based on the cost of the building, rent, or other floor space costs.

Finally, the cost of using one medium over another is influenced by operational costs. Operational costs may include the time required to load and unload media, time to configure and administer the software operations, and time required to restore backups or retrieve information from archives. Additional time may be required to label media and format media for use. Table 2 provides a simple worksheet that demonstrates a cost comparison between 4-mm tape cartridges and CD-ROM disks, for an example. The costs given in the table are for demonstration only.

Access Methods

Tape drives access data sequentially. This means that data are written to the tape and read from the tape as the tape passes the read/write heads on the device. To retrieve data from the tape, the drive must read the tape sequentially to find specific records for retrieval. This means that if a certain file or record is stored near the end of the tape, the access time will be longer than that for a file or record stored near the beginning of the tape.

Other storage media, such as disk drives, flash drives, and Zip drives store files in a way that allows random access. This means that a catalog is kept on the disk and the operating system can access the catalog to determine the exact location of the file so that retrieval time is minimized.

Summary

Some criteria for selecting storage media are more important than others. As an example, many organizations tend to focus on cost issues, but in some organizations, better operational reliability may be a more important factor than cost. Each of the criteria listed above should be considered with the perspective of the organization and its goals, to determine the weight of each factor on the ultimate decision.

MEDIA OPTIONS

Magnetic Tape

Technology breakthroughs in storage density and improvements in capacity occur frequently. Magnetic tape has been a reliable alternative for backups for many years, and despite improvement in other storage alternatives, tape continues to provide high-capacity, cost-effective, secure, easily portable data storage that meets the requirements for backup storage media in many organizations (Hein 2005).

Tape has the benefit of being a mature technology. As such, it is defined by industry standards such as the International Organization for Standardization (ISO) 1001:1986, which specifies volume and file structures, basic characteristics of blocks with records forming a file, recorded labels for files, and conditions for processes within information systems using recorded magnetic tapes. Tape is also available in a variety of formats, which are supported by multiple vendors, in several capacity and price ranges. Table 3 lists some of the tape formats available. The list is not exhaustive, but it shows some of the variety of options available.

Magnetic tape drives must be cleaned regularly. Each manufacturer provides guidelines for cleaning their drives. Normally the cleaning requires a special tape-cleaning cartridge and may require cleaning fluids as well. Tape cartridges are also susceptible to data loss if they are exposed to a magnetic field. Magnetic fields are generated by a variety of appliances, computer monitors, clocks, and desk lamps. It is important to store tapes in an environment away from magnetic fields, in a temperature- and humidity-controlled storage area (IBM 2003).

Optical Disks

Optical disks are manufactured in a variety of formats. Initially, optical disks allowed only one write operation, with the media being read as many times as necessary. This is referred to as write-once-read-many, or WORM, technology. Further developments in optical drives and media have produced optical devices that can be used multiple times.

Two popular formats for optical drives are compact disk (CD) and digital versatile disk (DVD). Both of these optical disk types are available in write-once and rewritable media.

The technology used in writing data to an optical disk incorporates some reflective media upon which a laser acts to change the reflectivity of the media. The reflective component of a CD-R disk is usually a silver, gold, or platinum alloy. The reflective element is coated with a dye, which changes the amount of light reflected by the laser, thus representing digital data. Dyes currently in use include cyanine, phthalocyanine, metalized azo, and hybrid dyes made from these three basic types. Each of these dyes has a different color characteristic when “burned” by the recording laser light and are patented by various companies that produce the media (McFadden 2006).

Media used in optical disk burners are different from media used in software or movie distribution. Media used to distribute software are created by mechanically pressing an image onto the media. This process is much more precise and accurate than the laser burning method used in current systems.

Optical media products vary in quality and reliability. One of the major differences in determining the quality of

Table 3: Magnetic Tape Format Options

Format	Brief Description
9-Track open reel tape	Virtually obsolete 1/2-inch tape
1/2-Inch data cartridge	Includes IBM 3480, Imation 9940, and other products
DLT (digital linear tape) cartridge	DLT tape is advertised to safely archive data for up to 30 years. DLT data cartridges hold up to 160 GB of data
SDLT (super digital linear tape)	SDLT storage media is ideally suited for data center and departmental backups for which capacity, performance and cost are critical. SDLT technology offers up to 300 GB of native storage capacity
LTO (linear tape-open) cartridge, -1, -2, and -3	LTO cartridges use linear multichannel, bidirectional formats with data compression, track layout and error correction code to optimize capacity, speed, and reliability. Storage capacity is generally rated up to 800 GB
DAT (digital audio tape)	Available from 12 GB up to 36 GB native capacity. Ideally suited for backup operations in small and medium-sized systems. DAT is a popular 4-mm helical scan medium for network and other backups. The DAT format supports random data reads and writes
Travan	Travan uses linear recording technology. Data tracks are recorded longitudinally in the direction of tape movement; this is the same technology as used by DLT tape drives. Only one motor is required to drive the tape, and the head moves only to change tracks at the beginning and end of the multiple recording passes. Capacity is rated up to 40 GB

the media is the quality of the dye used in the manufacturing process. Better dyes tend to be more stable over time, and provide a longer life for the media. Less expensive dyes result in a shorter life span and produce a larger percentage of rejected or unusable media (Laskey 2004). In addition to the initial quality of the dye, imperfections in the way the dye was applied to the medium during manufacturing can cause quality issues. If the dye was not spread uniformly over the medium, a condition known as dye thinning may occur. When the dye is not applied all the way to the edge of the medium (short spreading) the outer edges of the medium do not work properly. These dye-related problems usually cause the medium to be rejected during the recording or verifying stage, but may be realized only upon attempting to read the data later. Another problem with some poor-quality media is that some dyes cannot handle high-speed burns, and immediately deteriorate. Many of these problems can be avoided by using high-quality, branded optical disks for data storage (DigitalFAQ 2005). Fake, generic, and low-quality optical media are available from numerous sources, but the increased risk of losing data or monitoring every recording session for bad media frequently justifies the cost of first-class media.

Optical media should be stored in a temperature-controlled environment to prevent the deterioration of the dyes used in the media. Most manufacturers recommend temperatures between 20°C (68°F) and 4°C (39°F). Recordable optical media should be labeled using a non-solvent-based permanent marker, since adding paper labels to a medium can affect the balance of the medium and cause vibration and potential read errors when the medium is read. Bending or flexing optical disks can form stress patterns in the polycarbonate and may deform the reflective or recording layer of the disk, so care should be taken when removing the disk from a protective sleeve or jewel case (McFadden 2006).

Optical technology, like magnetic tape, is a relatively mature technology. It is also an evolving technology with advances in capacity, speed, and life span occurring regularly. When selecting any optical technology, it is important to consider how long the media will be stored. For example, daily backups are viable for only a short time, while archived information may need to be accessible for several years. As with any storage technology, as improvements are made, current practices should be evaluated in light of the availability of support for existing products. When newer products become more widely used, a migration strategy to the newer technology should be developed and implemented.

Hard Disks

Hard disk technology was originally developed in the 1950s. Since that time, the capacity and performance of hard disks has improved dramatically, and although the technology is mature, improvements are still occurring. Data are stored on a hard disk by dividing the disk into sections, then magnetically charging tiny segments of the disk surface. The magnetic charges represent digital data. There are some specific terms used to describe how a disk is divided. A hard disk contains multiple *platters*. Each platter is a thin, circular surface that is logically divided into

Figure 1: Hard-disk platter

concentric circles, or *sectors*. Each sector is divided into smaller units called *tracks*. Each track is formatted to hold a specific number of bytes of data. Figure 1 illustrates the sector and track concept.

Two of the important characteristics of hard disks are capacity and performance. Capacity is currently measured in gigabytes. Desktop computers are commonly available with hard disks ranging from 80 to 500 Gb per drive. Servers and large multi-user systems may have access to hard-disk capacity up to several terabytes of data. Hard-disk performance is based on the ability of the drive to transfer data to and from the disk to the computer. High-performance drives can transfer data at speeds of 80 Mbps and faster using data caches and wide data channels. The major limiting factor in data transfer speed is the rotational speed of the disk platter. The data can only be read from or written to the disk as the platter spins. Drive rotational speed is measured in revolutions per minute (RPM), and disks are currently available with speeds between 7200 and 15,000 rpm. Hard disks can be arranged in various configurations that provide fault tolerance, high capacity, and high performance. Some of the techniques for these arrangements are discussed in "Storage Area Networks Fundamentals" and "Storage Area Networks: Architectures and Protocols." A discussion of fault-tolerant technology for disk drives is in "Backup and Recovery System Requirements."

Hard disks are very reliable. A common measure of reliability for hard disks is mean (average) time between failures (MTBF). MTBF is calculated using one of two widely accepted standards. Most government programs use the MIL-HDBK (Military Handbook for Reliability Prediction of Electronic Equipment)-217 standard, developed by the military, and the Bellcore standard, which is based on the MIL-HDBK-217 standard, is used for other drive reliability predictions. MTBF calculations are based on predictions of failures of the components of a hard disk, not on actual failures (Case 2000).

Another aspect of hard-disk technology is that the disk must be formatted for use in a way that is compatible with the operating system. Part of the formatting process is determining which file system will be used by the disk. Some of the choices are listed in Table 4, with a brief description of each.

File systems provide several functions that make hard disks usable. One of the functions of a file system is user access. The file system works with the operating system to allow or deny access to files on the disk. Different operating system/file system combinations provide different levels of security, but the file system is an integral part of data security. Another function of the file system is that the file system determines the logical characteristics of

Table 4: File Systems for Hard Disks

File System	Brief Description
FAT32	File allocation table 32. Older file system for Microsoft Windows
NTFS	New Technology File System for Windows. Supports more security features, disk quotas, and larger volumes than FAT32
Ext2	Second Extended File System. Used in Linux systems
Ext3	Third Extended File System. Used in Linux systems. Provides support for journaling
GPFS	General Parallel File System. Proprietary to IBM. Scalable high-performance parallel file system for AIX 5L and Linux clusters

the disk. These logical characteristics include the maximum volume size, partition size, and number of levels of hierarchical structure that are supported by the disk. The file system may also handle read/write errors on the disk, and manage user quotas with information provided by the operating system (Shah 2001, 195).

Hard disks are used to store data from a variety of applications. In the desktop environment, personal computer applications and files are stored on the personal computer hard disk along with the operating system and utility programs. Organizations frequently use hard disks on a file server to store enterprise data such as databases and mission-critical application data (i.e., spreadsheets and policy documents). Larger computer systems store data on hard disks, including all of the previously listed files, and often use large disks for archival purposes.

Hard disks may also be used as a target medium for backing up large data sets. The advantage of using hard disks for backups is that transferring data between two hard drives is fast. The high throughput available by copying data from one hard disk to another hard disk tends to minimize the amount of time needed to complete the backup. Hard disks are also very reliable, and the risk of losing data because of media failure is minute. A disadvantage of using a hard disk for backups is that hard disks are less portable than other media. Disks with the fastest transfer rates and largest capacity are usually mounted in a computer or special appliance that is not easily transported offsite. This disadvantage may be overcome by transferring the data over a network to a remote site.

One of the choices available for remote storage, in a data storage or backup scenario is subscribing to data storage services from a storage service provider (SSP). An SSP provides remote disk space to an organization for a fee. SSPs offer security through encryption, guaranteed up-time, recovery services in case of disaster at the client site, and archiving services. Other advantages include not having to incur the overhead associated with having the actual disk drives on site, such as power consumption, hardware maintenance, space considerations, and human resource costs (Cummings 2006).

Removable Disks

This discussion of removable disks will be broken into three categories. The first category is the Zip disk. Introduced by Iomega in 1994, the Zip disk works like a floppy disk, but has a much larger capacity. Zip disks are available in 100-, 250-, and 750-Mb capacities. The disk requires a Zip

drive, which can be permanently installed in the computer or can be attached via a universal serial bus (USB) port (Delaney 2002). Iomega currently markets REV drives with removable disks rated at 35 Gb. These disks are frequently used for backups. The benefit of this technology is that the disks have a large capacity (up to 90 Gb when compression is used) and are easily transportable.

Another category of removable disk is a configuration in which a bay to receive the disk drive is installed into a computer or peripheral device, and the drive can be removed from the bay and reinserted without shutting down the computer (Miles 2003). This is also referred to as a hot-swappable drive configuration. This type of removable drive is frequently used in a RAID configuration. (RAID is discussed in more detail in Chapter 175, "Backup and Recovery System Requirements.") This category of removable drive is not usually used for backup and recovery purposes. The benefit of the device is that when a single drive fails, it can be replaced with a similar drive without interrupting system functions.

The third category of removable drives is the external disk drive. This drive is attached to the computer via a USB port or FireWire connection. Capacities for these external drives are comparable to those of internal drives. Although this type of drive could be used for disaster recovery, backups, and archives, many manufacturers market this category of drives as a medium for storing music, photos, computer games, and videos (Shaw 2006).

Static Memory

One of the most recent developments in data storage is the flash drive. This device is also known as a memory stick, USB drive, JumpDrive, Pocket drive, Pen drive, and Thumb drive. Flash drives are currently available in capacities up to 2 Gb. An advantage of a flash drive is that it can be used on any computer that is equipped with a USB port. Most computers sold today are manufactured with several USB ports. This means that the flash drive can be used on most computers, without the need for a drive such as a floppy disk drive or a removable hard disk drive. The device is about the same size as a car key and some users carry their flash drive on their key ring.

Some of the features provided in flash drives include a strap for carrying the device, a write protect switch (similar to the write protect switch on a floppy disk), and support to make the device bootable. Some flash drives also include encryption software. Most manufacturers do not specify an MTBF for their products,

but offer warranties ranging from 1 year to a lifetime (Woodward 2005).

Some of the common uses for flash drives are storing data that need to be accessed from multiple computers, backing up small amounts of data, and storing data that may not be allowed (because of policy or space restrictions) on a user's desktop computer. Users frequently use a flash drive for storing files that they need to access from multiple computers. If someone needs to take a spreadsheet home from work, a flash drive is a convenient way to transport the file home, and then bring the updated file back to work the next day. Flash drives are an effective backup device for small backup jobs. They are relatively inexpensive, fast, and easily transportable. In some organizations, certain files, such as music files are not allowed on employees' computers. In some cases, the organization may allow music files to be accessed from flash drives because this does not use up the hard disk storage space on the employee's personal computer.

Two of the security issues for flash drives are that the small size provides an easy method for stealing data, and the data on the drive itself may be accessed by anyone in possession of the drive. The first issue must be addressed by safeguards in the organization similar to safeguards used to protect data against theft from a floppy disk. These safeguards include hiring reliable employees, protecting access to data by requiring passwords, and encrypting data when necessary. It is also possible to reduce the risk of data loss by "locking down" USB ports on personal computers through operating-system-based security tools (Mellor 2005). Some manufacturers have addressed the second issue by password-protecting access to the data on the flash drive. In some flash drives, there is an area for storage on the drive that cannot be accessed without a password. Data may also be encrypted when stored on a flash drive for additional protection. Flash drives may also be a source of computer virus infection. One method that has been successful is to put a virus on a flash drive, then leave the drive in an area where it can be easily found. The natural response is for someone to plug the drive into their computer to see if they can identify the owner of the device. Opening a document on the device can spread a virus and the computer user could then spread the virus throughout the organization (Mullins 2005).

Summary

Each of the media options discussed above is suitable for different applications. Large data sets can be backed up using hard disks, or tape, and smaller data sets could use other options such as a flash drive or removable disk. When determining the best alternative, each of the selection issues discussed in the first section of this chapter should be considered.

HANDLING REMOVABLE MEDIA

The physical environment where media, particularly removable media such as tape and floppy disks are stored, can affect the viability of the media and the length of time the media can reliably store data.

Recommendations

The following guidelines may be helpful in getting the maximum life and reliability from removable media. Each media type has specific requirements, and the packaging should be consulted for recommended storage temperatures and operating conditions, but the following general guidelines apply to most removable media:

1. Store the media in a controlled environment. The ideal area is temperature- and humidity-controlled according to the specifications from the media manufacturer. For optical media, avoid sunlight and ultraviolet light, and store the disks in a dark area.
2. Return the medium to its storage case or container immediately after use. This helps keep the surface clean and free of dust and other matter that could damage the recording surface or drive.
3. Leave new media in the original packaging until it is needed. This protects the media from contamination from foreign objects or materials.
4. Avoid storing media near devices that might emit a magnetic field.
5. Before using a tape or disk, inspect it to make sure that there is no dust or dirt on the recording surface. If contamination is found, clean it according to the manufacturer's instructions before use.
6. Label the medium so that it can be easily found if needed. Special care must be taken with optical media (Byers 2003).

Media Rotation

Media used for backup or archival purposes should be evaluated periodically so that it is not kept in service past its ability to provide reliable data retention. In the case of a backup medium, it is common to reuse it several times, overwriting the existing data each time. This practice saves time and money, but if the medium is used repeatedly, it will eventually wear out or become unstable. Some backup software provides error logging, which can be useful in evaluating media. One option to consider is a planned number of passes or uses for a given medium. As an example, suppose the backup system for an organization uses tape cartridges. The manager, after consulting the manufacturer's specifications, might decide to designate five tapes for daily backups, one for each day of the work week. In order to provide an extra level of reliability, the manager may designate that the five-tape set will be totally replaced two times each year and the old tapes will be removed from service. This practice increases the probability that the tapes in service are viable. Other media rotation planning options should be considered based on the media used.

Security

One of the major advantages of removable media is that it can be easily transported. This advantage also increases the risk that valuable data might be compromised. Since it is very difficult to ensure that valuable data are not transported away from authorized areas, many security

specialists recommend that data be encrypted when stored on removable media. Of course, the encryption is useless if the perpetrator is able to obtain the encryption key, but this added level of security will protect against the loss of data from many potential threats. For a complete discussion of physical security, see "Physical Security Threats and Measures."

GLOSSARY

Checksumming: A mechanism that computes a value for a message packet, based on the data it contains, and passes it along with the data to authenticate that the data have not been tampered with. The recipient of the data recomputes the cryptographic checksum and compares it with the cryptographic checksum passed with the data; if they match, it is "probabilistic" proof the data were not tampered with during transmission. The important property of a cryptographic checksum is that, without knowing the secret key, a malicious interceptor has only an infinitesimally small chance of being able to construct an altered message with a valid corresponding checksum (Smith 1999, 270).

Cyclical Redundancy Check (CRC): A method of detecting errors in the transmission of data between two devices. A value is calculated for each block of data before it is sent and then the value is sent along with the data. A new value is calculated on the receiving device for the data. If the new value does not match the one that has been sent with the data, then a CRC error is reported.

Data Transfer Rate: The speed at which a device can write digital data to another storage device. The data transfer rates represent the highest maintainable speed at which the storage device can move data to the target media.

Disk Volume: A logical division of a physical disk. Usually a partition contains one volume. See *Partition*.

Duty Cycle: The proportion of time during which a device or system is used. The duty cycle may be expressed as a ratio (i.e., 2 hr/24 hr) or as a percentage (i.e., 20%).

FireWire: FireWire is Apple Computer's version of the IEEE 1394 standard for a high-performance serial bus, used in connecting devices to a computer. FireWire provides a single plug-and-socket connection on which up to sixty-three devices can be attached with data transfer speeds up to 800 Mbps (megabits per second). The standard describes a serial bus or pathway between one or more peripheral devices and your computer's microprocessor. Many peripheral devices now come equipped to meet IEEE 1394 (Sabetti 2003).

Partition: A logical division of a physical disk. In cases in which the user needs to organize his data into separate spaces, a hard disk can be set up to contain multiple partitions. In many cases, a hard disk is set up with a single partition.

INTRODUCTION

The concept of business continuity planning (BCP) identifies a set of technical, administrative, and management activities aimed at planning the steps to recover and restore critical business assets after an unforeseen event has impaired corporate functions. The BCP field has its roots in the 1970s, when mainframes and centralized data centers were designed so that the environment, access, and security could be controlled. Another advantage of this centralized approach provided a central environment that could be managed in such a way as to mitigate the consequences of external catastrophes (e.g., floods, fires, or earthquakes). For a couple of decades, such procedures and techniques took the name of disaster recovery (DR), emphasizing the fact that recovery and restoration activities were mostly focused on information technology (IT) physical facilities and assets that could have been damaged.

In the past decade, however, the way in which companies are organized and managed has changed dramatically, and DR requirements have changed accordingly to meet the new business requirements. In particular, the very nature of business assets has changed, first with the advent of personal computers and distributed systems, then with the expansion of Internet-based service-oriented companies, shifting from the provision of physical tangible goods alone to providing functions and services that could be operated in a wide range of different ways. Consequently, the former field of DR has grown in complexity to handle both old and new requirements and to comply with newer business models. For these reasons, since the focus has shifted from techniques solely to secure IT physical assets

to procedures and management strategies for ensuring the continuation of the business in its entirety, BCP has replaced DR as the discipline that describes how to face those unforeseen events that may impair the functions of modern networked organizations.

The goal today is the continuous availability of the business and its processes in its entirety—with the technology infrastructure taking a critical but no longer exclusive role—which gives an enormous importance to the time factor. That is, if down-time periods must be the shortest possible, then recovery and restoration must be as quick as possible.

This chapter is organized as follows. First, we discuss how the growing dependence of business-critical activities on the IT infrastructure affects BCP. The causes of down time are then explored, and in particular, we point out that modern organizations continue to be concerned with so-called small disasters (e.g., system failures, power outages, telecommunication interruption, and so on) and their management, which has modified the BCP focus in most cases. We then present the main characteristics of BCP and introduce the importance of a business impact analysis (BIA) as a fundamental activity for understanding the business needs of an organization and thus providing sound technical measures for recovering from disasters. In the context of BCP, we introduce the notion of risk management, which includes the need for analyzing and mitigating risks. We then present backups and alternate sites as the traditional techniques for data recovery and business continuity after the advent of failures. Emerging technologies like disk-to-disk backups and iSCSI (Internet SCSI) [small

computer system interface]) are also discussed. Important laws and regulations in the field of BCP are introduced. Finally, we discuss how BCP is evolving toward the more comprehensive notion of business resilience.

FROM DISASTER RECOVERY TO BUSINESS CONTINUITY PLANNING

For many years, corporations have placed most of their critical information assets into automated systems, and more recently, they have adopted business models largely based on the Internet. Although they provide more efficiency, cost reduction, and competitive advantage, these developments have also increased corporations' dependence on the IT infrastructure and therefore increased the potential economic losses caused by its failure. More than ever, a loss of access to the IT infrastructure will prove to be, in many cases, fatal for the business of affected companies. It is therefore crucial for companies to consider precise plans for counteracting possible events that may cause such interruptions. Examples of companies that failed to recover their businesses after a prolonged interruption of IT functions, caused by floods or fires, for example, are well known and documented (Hiles 2002; Kaye 2001; Noakes-Fry and Diamond 2001; Toigo 1999, 2001, *Fighting fires on the Web*).

E-business and Internet connections are shortening recovery time objectives (RTOs) and changing the way we think about DR planning; full 24/7 operations and zero down time are now commonly seen as business necessities. Although traditional countermeasures to natural disasters should still be provided (e.g., keeping backup data in locations out of the area possibly affected by natural disasters), a wide spectrum of other risks (e.g., cyberattacks) have to be considered. In addition, critical business processes must be analyzed and recovered much faster than in the past: down times of days (the usual time window for natural disasters) are definitely no longer sustainable for any company in general, and Internet-based businesses in particular.

Nevertheless, many enterprises still have minimal contingency plans in place to ensure business continuity for their business requirements. Managers fail to plan for DR in the new project development life cycle, which results in more risks and exposures than in the past. From a technological standpoint, some managers and planners still do not understand the intrinsic fragility of the new architectures for the e-commerce business to which they are migrating. Consequently, they do not understand fully the increased requirements for business continuity, do not plan for the inevitable failures, do not mitigate the risks, and are not prepared to sustain the consequences.

Downtimes in Business Services

Down times in business services might be caused by several things: equipment failure (e.g., disk crashes); disruption of power supply or telecommunications (e.g., blackouts, brownouts, or digging in areas where telecommunications/electrical lines are located); application failures or database corruption (e.g., inaccurate configurations or improper maintenance); human error (e.g., improper technical

actions); insufficient technical staff (e.g., strikes or coincident emergencies); malicious software (e.g., viruses or worms); hacking and Internet intrusions (e.g., random targets or specifically selected targets); fire; natural disasters (e.g., floods, earthquakes, or hurricanes).

Clearly, down times might be the effect of or worsened by a combination of causes. For instance, an emergency that could have been managed well without losses for the company may become catastrophic if it happens when key technical personnel are unavailable or are already busy solving another failure and recovery plans are non-existent. Problems may even arise as a side effect of events that do not affect a company directly. For instance, if a nearby company has an emergency, this event may impair the proper functioning or physical access to all locations in a certain area (e.g., incidents in chemical plants); this is called a "regional disaster."

Causes of failure can be characterized further based on two aspects: (1) the likelihood of occurrence and (2) the potential damage that they can provoke. These two properties reflect, respectively, a probabilistic and a quantitative description. For instance, events such as sabotage, floods, or fire, which are usually considered in traditional DR plans, are rare, but when they happen, they are often catastrophic. On the other hand, events such as equipment failures or software errors are less catastrophic in nature, but occur more frequently and represent almost day-to-day problems for system administrators.

Usually, these failures are not devastating for a company, and in the past (in the pre-Internet age), they were not included in DR planning. However, with today's companies relying more and more on networked systems, complex distributed multicomponent architectures, and the Internet as a primary business enabler, short but frequent down-time periods can become a major problem in terms of competition, reputation, and revenue losses (Bounds 2003; Toigo 2001, Storage disaster).

How to strike a balance in investing decisions between prevention measures focused on rare but catastrophic events and those focused on frequent but less severe failures is one of the most difficult challenges faced by modern BCP. In the old days, DR was focused only on the former; modern information security and system/network administration techniques are focused only on the latter. BCP should encompass both, thereby planning for all risks that may affect a company.

According to a study by the Gartner Group (Scott and Natis 2000), only 20 percent of down time is caused by technology failures including hardware (servers and network devices), environmental factors (e.g., cooling and power outages), and natural disasters. By contrast, 40 percent of down time is caused by application failures, which include software bugs, operating system crashes, performance slowdowns, incorrect updates, and changes to software. The remaining 40 percent of failures are due to human errors. In other words, according to these results, failures are mainly due to people and process issues, including software, whereas infrastructural components are more robust and reliable (Kaye 2001; Noakes-Fry and Diamond 2001, 2002).

These results should come as no surprise, actually. Applications frequently fail because of all sorts of

problems, including code bugs, bad design, weak requirement analysis, inconsistent tests, misconfigurations, erroneous installation or deployment, incompatibility with the run-time environment, and conflicts with other applications. Connectivity instead fails because of misconfiguration of devices such as routers, switches, or domain name systems (DNSs), sometimes caused by the company's staff and other times by Internet service providers (ISPs) and application service providers (ASPs).

Based on these figures, many experienced business continuity planners suggest that organizations select products and vendors with a good reputation of robustness and be skeptical about the latest products, because these products often provide exciting new features but at the price of less reliability and are less able to be recovered if a disruption occurs. Adopting a prudent approach is important for software products because they have been one of the principal causes of small disasters, but is of particular significance for infrastructural hardware components whose robustness and reliability impact on the whole organization.

BUSINESS CONTINUITY MANAGEMENT

Business continuity management (BCM) consists of a set of activities aimed at identifying the impact of potential losses, defining and realizing viable recovery strategies, and developing recovery plans for ensuring the continuity of business services. Disaster recovery planning is one of the components of a BCM plan and encompasses a set of activities aimed at reducing the likelihood and the impact of disaster events on critical business assets (NIST 2002; Toigo 1999; Wold 2002, Disaster recovery planning process—Parts I, II, and III). BCM planning is as complicated as any major system development project, with many stages of analysis and an overall activity set encompassing all critical assets, business functions, and technological solutions.

Convincing corporate management to invest in BCM planning is often a challenge greater than dealing with the technical problems of backing up critical systems, minimizing down time, and maintaining network connectivity. To complicate matters, investing in BCM capabilities is not a one-time event, but must be sustained over time, because every BCM plan needs to be tested, reviewed, and updated regularly to be effective. In addition, BCM planning needs to be managed, improved, and updated in synch with modifications to the company, its business environment, its IT infrastructure and critical assets, government and industry requirements, as well as personnel changes. For these reasons, management consensus is vital for every BCM plan that, in the best of circumstances, will enable failure avoidance, detecting and reacting to potential problems before they become disasters.

BCM plans should be documented adequately with an in-depth analysis of the risks addressed in the plan, the benefits for the corporation, the possible impact on revenues of an insufficient BCM plan, the estimates of the cost of down time, and the possible savings on insurance costs (Kaye 2001; Toigo 1999).

The process of managing business continuity, in a classification scheme inspired by the *Business Continuity*

Management—Good Practice Guidelines (BCI 2005) of the Business Continuity Institute, has these five phases:

1. understanding the company's business
2. recognizing the risks to business activities
3. developing recovery strategies, such as backup, alternate site, or replication
4. exercising, rehearsing, and periodically reviewing the DR-BC plan
5. creating a BCM plan

Understanding the Company's Business

Understanding a company's business requires an analysis of the operational aspects of the company. This analysis should determine what are the key business objectives and the products or services of the business objectives, when the business objectives should be achieved, who is involved in the achievement of business objectives, and how the business objectives are achieved. This analysis should result in the clear identification of mission-critical activities. Elements of mission-critical activities are human resources, stakeholders, suppliers, customers, facilities, functions, processes, materials, technology, telecommunications, and data. In addition, for each mission-critical activity, it is necessary to identify single points of failure—elements or components for which no alternatives exist.

The business impact analysis (BIA) and the risk assessment and analysis (RA) jointly address all these issues.

Business Impact Analysis

The BIA encompasses activities aimed at identifying, quantifying, and qualifying the business impact and other effects of a mission-critical activity failure on a company. The fundamental outcome of the BIA is the identification of the minimum level of resources needed to accomplish the company's business objectives in terms of an acceptable recovery time—recovery time objectives (RTO)—and an acceptable recovery status of assets: recovery point objectives (RPO). The outcomes of the BIA can then be summarized as follows:

- Identification of mission-critical activities, along with their dependencies and single points of failure
- Financial and nonfinancial impacts of a disruption, failure, or loss of one or more mission-critical activities for a given time frame
- Recovery priorities for each mission-critical activity based on the criticality of resources and on the associated sustainable time window and cost considerations (Prioritizing recovery strategies can optimize allocations and expenditures for the recovery process.)
- Recovery objectives in terms of RTOs, RPOs, and the minimum level of acceptable business continuity to sustain the company's operations
- Work area recovery, the minimum level of resources necessary to achieve the recovery objectives according to the resource recovery objectives of each mission-critical activity

The BIA should involve staff members from most, if not all, areas of the company. For instance, business managers are better able to analyze business impacts, either financial or nonfinancial, and should provide initial input as to the recovery priorities required by their business areas. Senior management should be involved in making the final determination of the recovery priorities among mission-critical activities.

Evaluation of Losses: Tangible and Intangible Costs

To evaluate how much down-time periods may cost, companies must consider all the components that comprise their business and how each may be affected by system failures, including not only lost current revenues but also the loss of any future or potential revenues. Because many companies today have structured their organization across interdependent business units and have extended their supply chains, the impact of down time may spread through many interconnections, and hence grow rapidly. No longer restricted to a core business, businesses may experience the effects of down time on related businesses, partners, and customers all along the value chain.

Moreover, companies' increasing reliance on a few business-critical technologies is another aspect that increases the severity of the impact of down time. Internet-based companies, which require connectivity and availability of their Web sites 24 hours a day, 7 days a week, 365 days a year, are in such a situation—they are completely based on Internet connectivity for their business, which has made them the victim of unforeseen problems. In the past few years they have suffered all sorts of system and/or network outages and have been threatened by distributed denial-of-service attacks. A classification of costs should divide them into tangible and intangible costs (Merchantz 2002), which we discuss next.

Tangible Costs

Tangible costs are easily identified and are often (though not always) easily measured, and may include the following:

- *Lost revenue:* This is the most obvious cost, as the company cannot conduct business, and balance sheets state that unmistakably. Just looking at normal hourly sales and then multiplying that figure by the number of hours of down time provides a good estimate of lost revenues. However, this must be regarded as only one component of the total cost of down time and, taken singularly, normally underestimates the true loss greatly. E-commerce companies amplify the problem because a company normally has no alternative way of conducting business and depends entirely on system availability.
- *Lost productivity:* During down time, production is blocked, and productivity lowers to zero. The same applies even when production is not blocked completely, but is just impaired, because employee productivity is still affected. Evaluating lost productivity is difficult because production normally does not stop completely

and employees might then engage in different duties. One way to obtain an estimate is to compute the cost of salaries and wages for the time frame of the down-time. Productivity value is normally higher than labor costs; hence, this figure represents a conservative evaluation of what a company has lost during down time. In addition to pure labor costs during down-time hours, one should consider that, after the recovery effort is completed, employees will not simply go back to their normal duties, but some will probably be in charge of other recovery actions (e.g., data reentry). This represents either additional costs (e.g., if done on an overtime basis) or less productivity (e.g., if done by taking time away from usual work).

- *Late fees and penalties:* Some companies work under contracts, normally called "service-level agreements," that include penalties for late deliveries. If system down time causes these companies to miss their contracted delivery dates or users cannot access data made available by an Internet-based company, the penalties incurred are another cost of down time.
- *Legal costs:* Depending on the nature of the affected systems, there could be legal costs associated with down time. For example, a drop in the share price may induce shareholders to initiate a class-action suit if they believe that management was negligent in protecting vital assets. Other examples of legal costs are cases of business partnerships in which the failure of one company affects the business of the others or of defective products delivered as a consequence of a system failure. In addition, some public utility companies could be considered legally responsible for the suspension of a public service because of a lack of sufficient precautions and failure prevention. Evaluating possible legal costs is extremely difficult because legal aspects are complex and are strictly related to the specificities of any single case. Experiences or historical data from companies in the same business sector could give a broad estimate. For a more specific evaluation, a legal consultant should analyze in detail the risks the company may face.
- *Other costs:* Many other costs could arise, which are often specific to the particular industrial sector. For example, a fresh food producer could be forced to discard perishable goods, a manufacturer may incur costs when restarting automatic machines, a construction company may have leased machines for which the leasing period must be prolonged, and so forth.

Intangible Costs

Intangible costs, by nature, are neither easy to identify nor easy to measure, but they affect the business just like tangible ones and have been the most critical cost factor in recent years in the BCM field. Think, for instance, about the impact of a system failure on the company's brand and reputation. The brand value does not appear in any balance sheet, but it is often one of a business's most valuable assets. There are statistics and analyses (Hiles 2002) that correlate how the devaluation of a reputation of a company suffering a disaster affects the share price. According to these studies, the share price of a corporation suffering a disaster falls by about 5 to 8 percent within the

first few days after a disaster. This decline is reasonable, because stakeholders may consider their investments to be in danger.

What is interesting is how recovery of the share price depends on the efficiency in recovering critical business functions. Past cases have shown that efficient recovery has enabled companies to regain the confidence of financial analysts quickly, and their share values have climbed back to the prices preceding the disaster, even increasing by 10 to 15 percent in the following 100 days. Companies that recovered with many difficulties, instead, were penalized with declining share values, about 15 percent on average (Hiles 2002). These facts demonstrate how a company's reputation affects tangible items such as the share price, not only permitting a company to rapidly regain share prices held before a disaster but even improving on those quotes. An inefficient recovery, in contrast, harms the company's reputation, which may have a perverse effect on share prices.

Another intangible cost is lost opportunities. During a down-time period, potential customers who would have been conducting business with the company suffering the failure may choose a competitor. This lost opportunity not only causes an immediate loss but also may have persistent negative effects because those customers could be lost forever. Calculating such loss of future revenue is very difficult. Historical data showing the rate of new customers in a given period could provide a broad estimate.

After recovery, the company's management might be forced to initiate an expensive corporate image and marketing campaign and a promotional campaign with significant price discounts to regain the confidence of customers and rebuild its reputation. The cost of such promotional and marketing campaigns can be evaluated precisely and must be taken into account as possible additional costs of down time.

RISK MANAGEMENT

Risk is defined as the possibility of suffering harm or loss, and *risk management* is the process of planning for such eventuality (Wold and Shriver 2002). The goal of risk management is not to eliminate all risks (which would be impossible in practice), but rather to find an acceptable balance between reducing risk and preparing the organization for losses. The risk management process has three steps:

1. *Risk analysis*: Identify the types of losses that may occur, determine the causes and the likelihood that a loss will occur, and estimate the resulting cost for the organization.
2. *Risk mitigation*: Identify actions to reduce or eliminate the likelihood of occurrence of each risk, determine the cost of those actions, and produce a cost-benefit analysis of the actions for each risk and loss.
3. *Risk transfer*: Address the losses that may occur despite preventive actions and consider transferring those losses to insurers or third parties, such as service providers, vendors, or outsourcers in general.

Risk Analysis

A risk analysis includes these activities:

- Identify existing risks to mission-critical activities resulting from the BIA. For each mission-critical activity, threats and their possible sources should be identified.
- Establish the likelihood and impact of each possible threat. This analysis is needed for defining priorities and planning for preventive measures and recovery actions. The clear identification of the relationship between the likelihood and the impact of each risk is a key component.

Define BCM strategies for each failure cause, which means that the BCM planner must define approaches to manage the risk and estimate the trade-off between sustaining the possible losses and implementing a preventive strategy.

Risk Mitigation

Risk mitigation is a process aimed at limiting the likelihood of risks and the potential losses those risks can cause (Kaye 2001). The process of mitigating risks can be summarized as follows:

- *Avoid the causes*. Make conservative and prudent technology choices for critical assets: avoid technology risks by developing services in a robust manner and with the support of reliable platforms instead of adopting the latest technology without testing it for reliability (which is usually riskier), unless it has been proven to give a sensible competitive advantage.
- *Reduce the frequency*. All IT infrastructure components should be chosen based on their ability to ensure a low rate of failure. Operating systems and software/hardware platforms of different vendors (or different versions produced by the same vendor) often have different failure frequencies. To enforce the risk-management strategy, reliability, and not just performance and features, should be evaluated carefully when purchasing technology.
- *Minimize the impact*. Because the frequency of failures and outages can never be reduced to zero, a risk-mitigation strategy should analyze all the possible single points of failure, the failure of which may cause major losses in terms of down time and extent of service interruption. Redundancy is the typical strategy that can be applied to servers, network devices, and internal components.
- *Reduce the duration*. Minimizing the duration of down time is the ultimate goal of every DR plan—the longer the down time, the greater the loss of revenue. Many strategies can be adopted to speed up the recovery of data and functions. These may involve onsite hardware spares, onsite staff, efficient backup solutions, and alternative operating locations.

Risk Transfer

Risks that cannot be sustained by a company can be transferred to a third party that then assumes the risks in

exchange for a service fee (Kaye 2001). Hiles (2002) estimated that, on average, up to 40 percent of actual losses could be transferred, but no more than that. Risk transfer can assume two forms: insurance or outsourcing.

Insurance is the traditional way of transferring risks that cannot be mitigated with in-house solutions or transferred by purchasing the service outside. Most insurers offer coverage even for risks related to Internet-based threats, such as intrusions or denial-of-service attacks.

With outsourcing, a third party provides a specific service in place of an in-house solution. This third party can then assume the risk of losses that the company may incur, either by refunding the fee paid by the company (as in the case of Web-hosting services) or reimbursing the losses (as in the case of vendors). Risk transfer is established via a contract that usually includes a service-level agreement (SLA) that should guarantee a minimum level of service to the company that purchases the service.

Risk transfer is a suitable solution in many situations, but the trade-off between the cost of possible down time, if the service is realized in-house, and the cost of the purchased service with a certain quality level should be evaluated carefully. A careful evaluation of the return on the outsourcing investment should therefore be completed to determine whether the strategy is convenient (down-time costs versus service fees). Consider, for example, networked services, Web hosting, and mainframe hosting, for which outsourcing is the common choice today.

When purchasing a critical service from a vendor instead of managing it in-house, the company signs an agreement concerning the level of service guaranteed. The parties agree on a certain up-time guarantee, expressed as a percentage of time of availability (usually a value between 99 and 100 percent) of the purchased service. Clearly, the higher the up-time guarantee, the more costly the service, and after a certain percentage of up-time guarantee, the cost that a company would pay for a given service level is not worth the benefit gained. Penalty clauses are normally defined in the SLA, which charges the ISP with monetary fines if it is unable to comply with the up-time guarantee. However, because there are loopholes in SLAs that can be exploited for the benefit of the service provider, legal clauses defined in the SLA should be reviewed carefully. Many ISPs promise an up time of 99.99 percent, but do not actually comply with their claim because of a host of limitations related to infrastructure, government policies, inefficient resources, etc.

BACKUP, RECOVERY STRATEGIES, AND CONTINUOUS DATA PROTECTION

Traditionally, backup has been seen as a batch process, running during night hours, which stores on tapes all relevant information produced during that workday. Although this process is still used and is necessary for the majority of organizations, in many other cases it is now outdated. With the increase in Web-based services and service-oriented architectures (SOAs), applications and business processes tend to be active on a 24/7 basis. Therefore, there is no longer the notion of "night hours," which was meant to be that window of inactivity of business transactions perfectly suited to take a snapshot of data. In many

real-world scenarios, transactions are always running, and information is always accessed and possibly updated. In addition, the amount of data to be managed is growing every year at a terrific rate. Many commentators refer to the ever-growing amount of data that need to be managed, backed up, and restored as "the explosion of data," to emphasize both its impressive growth and chaotic nature (Campbell 2000; Kaye 2001; Nicolett and Berg, 1999; Toigo 2001, *Fighting fires on the Web*).

Recovery strategies are one of the most dynamic areas of BCP. Beyond traditional backup and recovery solutions, more sophisticated data storage and network recovery technologies are emerging, pushed by recovery speed and data availability requirements that are becoming increasingly severe. Continuous data protection (CDP) is the newest concept and most ambitious goal of BCP for what concerns data availability and recovery strategies. Despite the lack of a rigorous definition of CDP and formal standards—the Storage Networking Industry Association's (SNIA) Data Management Forum (DMF) is still working on such a definition—vendors are stressing CDP as an essential BCP practice for modern enterprises. For example, CDP has been described as "fine-grain, point-in-time views of data and applications for the purposes of data recovery," or as a function that lets "data [be] protected as close to instantaneously as [possible] after creation, and should the primary copy become unavailable, the system needs to automatically and transparently fetch one or more copies of that data" (Kerner 2005). The purpose of CDP is evident from these two statements: the highest granularity, both in time and in content, in the selection of data to be recovered; and the immediate availability of data when needed, achieved with the highest degree of automation and transparency. In more detail, what makes CDP different from previous recovery strategies is that CDP should provide continuous recovery points, so that it should be possible to roll back from *any* point in time, instead of from a *single* point in time as for traditional recovery technologies. Considering technologies, CDP is not seen as a revolutionary idea that would bring solution alternatives to the current ones. Instead, it is perceived as the concept that could drive the development of the next generation of recovery technologies, incrementally enhancing current solutions, like data snapshots and virtual tapes, and integrating them in coherent CDP-oriented data-protection frameworks. By means of such frameworks, the traditional batch-mode way of dealing with data recovery should be abandoned in favor of more proactive systems able to meet those data availability requirements needed by modern business models. The CDP's goal is ambitious, indeed, and although it is still not clear how achievable it will be, for which contexts it will be well suited (business categories, enterprise types, etc.), and to what extent it will be worth it (in particular, analyses investigating the economic and financial basis of such recovery solutions are yet to come), most of the advances in storage technologies are based on CDP premises.

Fundamentals of Backup and Recovery

Key to an effective recovery of business functions is the availability of all the company's data, as well as the reconfiguration of all critical components of the IT

infrastructure (e.g., backup of servers and network devices configuration, patches, passwords, routing tables, and firewall rules).

Backup and recovery of data should achieve two fundamental goals:

- Backup should be completed with a minimal impact on the production environment and, ideally, should be performed without blocking transaction execution.
- Recovery should be efficient, so as to minimize the time necessary to restore the data and bring the system back to its operational state. The efficiency of the recovery process is a key factor for the effective restoration of the company's business functions, as a delay in recovery could cause a severe loss of market share.

Although the need to maintain backup copies of data is well recognized, many companies overlook the need to make a copy of system configurations. This requirement is overlooked so frequently because of its intrinsic organizational nature: system management and day-to-day administration of the IT infrastructure, such as a change in routing tables or firewall rules, installation of patches, or the like, must always be documented fully to be backed up. In addition, procedures should be put in place to make sure that every modification to system components—the ones needed by mission-critical activities, at least—is reported in backup copies.

Some consideration should be devoted to the particular backup requirements of desktop computers and portable systems, which have some peculiarities with respect to servers. Often the data backup process for these systems is not automated (e.g., saving data on backed-up file servers), so it is a duty of users to manually save critical data on backed-up servers. This good practice should be governed by an appropriate usage policy (i.e., a documentation possibly subscribed to by each user stating, among other things, that each user should take care of saving his or her critical data on a backed-up server and not locally). Intermediate managers should enforce this policy, devoting particular attention to having training sessions during which users should be instructed about the importance of this recovery requirement. Providing an automatic backup and restoration process for personal computers requires interoperability and platform standardization. Usually recommended are homogeneous platform operating systems, configurations, and applications among the organization's personal computers and portable devices (NIST 2002).

Alternate Sites Strategy

In addition to the safe storage of data backups, it is necessary to provide an organization with a plan for the continuation of its business functions if its primary site suffers severe damage. A DR plan should then include a strategy to recover and perform system operations at an alternate facility. Generally, three types of alternate site strategies are possible (NIST 2002):

- dedicated site owned or operated by the organization
- reciprocal agreement with an external entity (e.g., a business partner)
- commercial leased facility

As prospective alternate sites are evaluated, the DR planner should ensure that the system's security, management, operational, and technical controls are compatible with the prospective site. Controls may include measures for network security, such as firewalls and intrusion-detection systems, and physical access controls. If the service is purchased from a vendor, an SLA must be negotiated carefully. It must clearly state all conditions, such as testing time; workspace; security, hardware, and telecommunication requirements; locations of facilities; support services; declaration procedures; and recovery time frame.

The DR planners should be aware that a commercial facility usually hosts many customers, which may all be affected by the same natural disaster simultaneously. Hence, the commercial facility could be asked to recover several customers simultaneously, but might not have enough resources to do so properly. In that case, the commercial facility would tend to set priorities among its customers and not treat all of them at the same level of service. Unfortunately, this scenario is realistic, and for this reason it is extremely important to negotiate a clear and extremely detailed SLA with the commercial vendor, with defined legal and penalty clauses that address how possible disasters will be handled and how priority status is determined.

Regardless of the type of alternate site strategy used, commercial facilities provide different services and have different levels of readiness with respect to the goal of immediate resumption of all business functions. The following classification of facilities also reflects the different commercial services offered on the market (NIST 2002; Nicolett and Berg 1999; Toigo 1999):

- A cold site typically consists of a facility with adequate space and infrastructure (electric power, telecommunication connections, and environmental control) to support the IT infrastructure. However, the cold site contains neither IT equipment nor office automation equipment, such as telephones, fax machines, or copiers. The organization leasing a cold site needs to provide all the necessary equipment.
- A warm site is a partially equipped office space containing some hardware, software, telecommunication connections, and power sources. The warm site is kept in an operational state so it can be promptly made fully operative in the event of a disaster at the company's main site.
- A hot site is a fully functional and immediately ready facility equipped with all the needed hardware, software, telecommunication connections and equipment, and power sources. Hot sites are usually staffed 24 hours a day, 7 days a week. Recovery of business functions is guaranteed to be extremely fast.
- A mobile site is a self-contained, transportable shell equipped to restore immediately the subset of the most critical business functions, including telecommunication facilities. Major commercial vendors lease these mobile sites and keep them located in strategic places to enable them to reach most of the industrial plants in a relatively short time. However, to guarantee an on-time recovery, a company should sign agreements with vendors to have the mobile site ready in a time frame compatible with its business requirements.

- A mirrored site maintains an almost exact replica of the IT infrastructure of the company's main site and is always ready to recover all the business functions. Recovery is almost immediate through a mirrored site. It is usually owned and operated by the company, given the high degree of customization and specificity required.

The above solutions differ in terms of their cost and timeliness. Cold sites are less expensive to maintain, but require that the business expend considerable time to acquire and install the necessary equipment. Going down the list, we find solutions that are more expensive, but provide greater availability.

Trade-offs in the Offsite Location Choice

Backups should be kept in a safe place, where they cannot be affected by the consequences of a disaster; doing so enables their recovery in the event of a disaster that compromises or makes their original data unavailable. This has been for decades DR's golden rule, especially for mainframe-centric IT infrastructures. Effective recovery requires that in addition to data, even media for custom and purchased software together with their license information be kept offsite. Last, but not least, all documentation related to the BCM and DR plan should be backed up. It may seem obvious that BCM documentation and plans need to be available when an emergency calls for its activation, but this might not be the case if they are not kept in a safe and reachable place (e.g., offline at an alternate site).

However, although the necessity of maintaining backed up assets in a safe place is unanimously recognized, how to evaluate the safety of the offsite location, and in particular how to balance the trade-off between safety of the alternate location and physical availability of recovery data, accessibility of the secondary site, and costs of the offsite setup has proved to be not that clear. Anecdotal experience shows that it is easy to find apparently illogical situations like, for example, secondary sites two blocks away from the primary site—and likely to be affected by the same consequences in case of disasters—or offsite locations hundreds of miles far from the main one or in locations difficult to reach and poor of IT infrastructures, so that while safety is achieved in case of a disaster, the same cannot be said about the ability to effectively restore business operations at the secondary location.

There is not an unanimously recognized standard; however, as a rule of thumb, a distance of about 35 miles between the primary and the secondary sites—which is almost the size of an MAN (metropolitan area network)—is a reference value accepted by many (Robb 2005). That reference value should, of course, be considered as a gross estimation of the needed distance, which could vary considerably according to the risks that are taken into account. For instance, if risks are those derived by small disasters, that distance could be greatly reduced because it is extremely unlikely that the same small disaster is able to hit both sites at the same time. More in general, and considering especially those risks typical of disaster recovery situations, there could be cases in which a distance of about 35 miles is not sufficient. Devastation

provoked by Hurricane Katrina is only the latest example of a disaster that hit an area much larger than 35 miles. Another documented case was when after the events of September 11, 2001, several U.S. agencies suggested a 200-mile plus separation between the primary and secondary facilities.

Despite these counterexamples, the point that must be stressed once again is that safety is not the only requirement. Availability, costs, and technological limitations must be taken into account. For instance, about the 200-mile plus recommendation, there was an inescapable problem in complying with it because of the fact that there were no technological solutions able to support such a distance—or if a few could be close by, they came at enormous costs—providing not simply backup copies' safety but also backup efficiency, recovery availability, and synchronous updates of large-scale transactional databases and other applications without a large performance hit. Only very recently have advances in IP SAN (Internet protocol storage area network), which we will discuss in the following, have been able to reach distances of several hundred miles, providing, at the same time, good efficiency. Costs for such solutions are, however, still very high. This simple case witnesses one of the biggest difficulties of modern BCP: solutions are no longer specific for a single requirement (e.g., data safety) as they were, sometimes, for DR in the past. On the contrary, BCP must strike a balance between many different and often contradictory requirements, maximum safety and easy accessibility, immediate availability and affordable costs, and best efficiency and high level of integration, to name just the main ones. BCP solutions inevitably have to accommodate all these needs, and from here it is easy to see why in the BCP field, more and more people stress the fact that there are no "one-size-fits-all" solutions (solutions not tailored to the needs of the specific context in which they will be applied). This way, all the trade-offs between different requirements are resolved without taking into account the peculiarities of the business, of the organization, of the market, and of the environment, leading to a BCP solution that inevitably does not fit with the context to which it will be applied.

STORAGE TECHNOLOGIES FOR DATA BACKUP AND RECOVERY

Well-Established Technologies

Some of the conventional, well-established, and experimental technologies for backing up data are summarized by Toigo (1999) as follows:

- *Server image backup*: Image backup creates a physical image of an entire disk. It operates at the physical disk level by transferring sectors of physical data storage blocks from hard disk to tape. It has fast transfer rates and provides complete server backup by transferring the entire contents of the hard disk as a single unit. This technology requires the system to be inactive during the backup.
- *Snapshot or versioning backup*: This technique is fast because, after an initial complete image backup,

it proceeds incrementally by backing up the modifications only. It works with block-level copies on a partition basis. It is widely used in traditional tape-based backup systems.

- *Full volume backup on a file-by-file basis:* Complete data sets are copied over the production network to backup devices. A process controlled by the server initiates the transfer to backup devices.
- *Incremental or differential file backup:* Files are compared with their version in the preceding backup, and only the changed files are backed up again. Differential backup keeps separate versions of the same backed-up files, whereas incremental backup keeps just the newer version.
- *Backup using object replication:* Software defines logical objects, including disk partition tables, boot volume, security information, system volume, and user data volumes. Logical objects are regarded as a single logical unit, and all data can be copied at once.
- *Electronic tape vaulting:* This process replaces the manual procedures for handling tapes stored in off-site storage facilities and for moving tapes between locations. To provide for immediate access to data stored on tapes, it exploits a wide area network (WAN) connection between the company facility and the offsite facility where the tapes are stored. Technologies such as shadowing and multiplexing controllers allow the simultaneous duplication of backup data streams in two or more tape devices. This way a company could make both a local backup (for complete recovery in the event of a disaster) and an electronic vaulting on a remote storage facility (to preserve data from a disaster, such as a flood or fire that affects the company site).
- *Remote disk mirroring:* This is another alternative to handling tapes physically. The content of disks is duplicated in near real time to a remote disk volume. The same concept is applied to redundant array of inexpensive disks (RAID) technology as a means of fault tolerance, rather than disaster recovery.

Making use of an offsite storage facility is the safest choice for preserving backups. The remote storage facility should be in a location that is unlikely to be affected by the same disasters that might affect the main company site. It could be a branch of the company or a commercial system recovery facility offering this service. Although companies with decentralized sites could choose to keep backups in their different sites, commercial storage facilities offer backup storage as a service, including media transportation, safe storage, and recovery (Nicolett and Berg 1999; NIST 2002; Toigo 1999).

Remote Mirroring

Remote mirroring techniques form the basis of many commercial systems aiming at safeguarding corporate data and providing fast recovery. However, sometimes the expectations that planners place on remote mirroring solutions are not realistic. In addition, solutions based on remote mirroring tend to be complex, both architecturally and in data management, so that they can satisfy the high

requirements from companies. This complexity may lead to a lack of robustness of the recovery system, incorrect configuration, and improper array maintenance. The consequence could be the loss of synchrony between arrays or the storage of corrupted data. If this happens, a recovery could result in a multiplication of the disaster because it runs the risk of recovering corrupted or incoherent data (Kaye 2001; Toigo 2001, *Fighting fires on the Web*, 2001, Storage disaster). In addition, remote mirroring does not allow zero down time, which is considered a requirement by some senior managers. Remote mirroring, if configured properly and implemented with high-level technology, can be much faster than many other recovery alternatives, but it cannot reduce the down time to zero. Hence, remote mirroring is not the panacea that makes the nightmare of down time disappear: risk management and DR planning are still mandatory. Moreover, remote mirroring is subject to data gaps, because some sort of asynchrony is usually implemented (e.g., the mirroring between the secondary and the tertiary arrays of Figure 1). Possible consequences of incoherent recovered data should be analyzed carefully in the planning stage. Such data may provoke the loss of commercial orders, payments, or shipments, if data gaps are not identified and handled properly. Solutions designed to be completely synchronous do exist, but come at high prices in terms of performances and system latency. In fact, the problem in remote mirroring has traditionally been the latency caused by the distance, possibly many hundreds of miles, between the sites, in particular when the mirroring is synchronous (i.e., writes to production disks wait for the mirrored writes to be completed and acknowledged).

Starting from the mid-1990s, the cost of high-speed bandwidth WAN decreased and vendors realized architectures that made remote mirroring one of the best solutions at an affordable cost for many companies. The typical improvement provided for three arrays, adding an intermediate site between the company and the final remote storage facility (Toigo 1999). Figure 1 shows the traditional and the enhanced schema for remote mirroring. The benefit of the enhanced schema is twofold. First, the link between the company site and the secondary array could be a high-speed serial one, thus reducing the latency in synchronous mirroring. Second, the mirroring between

Figure 1: Remote mirroring configurations

the secondary and the final arrays, connected with a WAN, could be realized asynchronously, hence optimizing the mirror operation while not affecting the robustness of the DR solution.

Disk-to-Disk Backup

Disk-to-disk (D2D) backup technology is fast, efficient, and automatic and is able to respond to most of the current need for speed in terms of business continuance. D2D is the practice of protecting data using hard disk as a primary backup medium rather than tape technology. This contrasts with traditional approaches to backup that consist of a backup application, a backup server, tape libraries, tape drives, and media. D2D backup solutions, instead, integrate hard-disk technology and systems into the backup function to serve as the primary target of the backup application, complementing tape drives and libraries that focus on the archive function. The performance advantage is evident in terms of speed of backup and speed of restoration of backed-up data. It should be noted, however, that D2D technologies are not really new, because hard disks, the serial advanced technology attachment (ATA), and tape emulation have been IT tools at least since 1992, with products designed for block-level mirroring for quick restore and incremental backup. What makes today's D2D solutions attractive is the new emphasis on BCP and the ever-growing call for more speed and cost containment. D2D integrates tape-based backup architectures by inserting a new level of backup that fosters speed in storage and recovery. Then, on the backup disk, data can be filtered and managed so that only selected information, for instance, is then subsequently moved to tapes.

Cost of D2D solutions is the other motivating factor. In fact, the major complaint about D2D—its expense—has no more reason to hold with the advent of increasingly resilient and decreasingly expensive ATA and serial ATA arrays. Decreasing costs combined with innovative features of D2D technologies benefit from new algorithms that factor out replicated data on multiple primary disk platforms, copying only one occurrence of the data and thereby reducing the size of the data set that needs protection. A metadata repository of the data that is mirrored is normally maintained so that it becomes possible to roll back to any point in time and to return data to a usable form.

In a sense, the D2D approach, especially when combined with technology to replicate data in caching appliances at multiple locations within the enterprise network, represents the new generation of remote mirroring solutions, in which the very concept of mirroring is surpassed in favor of a vision of systems as synchronized caches that afford fault tolerance to the entire enterprise environment.

However, D2D solutions have not yet come into the mainstream, and the many promised benefits still have to be demonstrated. In particular, D2D technology must be tested in complex and critical scenarios in order to prove not just their speed but also their reliability and robustness.

To this end, what happened in 2002 is not encouraging. Vendors concerned with the many configurations of

D2D founded the EBSI (Enhanced Backup Solutions Initiative). EBSI gained wide consensus among consumers, but was first blocked, then absorbed, by SNIA. Little has been done since to evaluate and compare data-protection solutions appearing in the market.

Storage Area Networking

Let us introduce some basic definitions of the key network-based storage technologies (Steinberg 2002, Kaye 2001):

- *Direct Attached Storage (DAS)*: DAS requires that all storage access methods involve a central processing unit (CPU)/server, with requests sent over an input/output (I/O) bus such as SCSI or integrated device electronics (IDE). As a result, DAS storage devices are tightly coupled with the host computer's operating system, and distance limitations come into play. DAS devices can be physically inside a server or external to it.
- *Network Attached Storage (NAS)*: NAS describes a specialized file server and storage device connected to a local area network (LAN) hub or switch. Client machines mount volumes (i.e., disks of the server) to transfer data files to local machines.
- *Storage Area Network (SAN)*: A SAN is a dedicated, high-performance network infrastructure optimized to move large amounts of data for applications that require optimal performance, redundancy, and availability. SANs provides scalability, accessibility, manageability, and fine-grained data selection. Most of all, SANs greatly extend the distance of a peripheral channel with respect to NASs that are bounded to LANs.

Among storage technologies, the SANs in particular have gained wide acceptance—SANs amount to almost 50 percent of the current storage solutions on the market. A SAN is a specialized, high-speed network attaching servers and storage devices using network devices, such as routers, gateways, hubs, and switches. Its main benefit is that it eliminates dedicated connections between servers and storage devices. The most common SAN technology is fibre-channel networking with the SCSI command set. A typical fibre-channel SAN is made up of a number of fibre-channel switches that are connected together to form a fabric or network. Moreover, a SAN also eliminates all restrictions on the amount of data that a server can access. A server is enabled to share a common storage environment, which may comprise many storage devices, including disk, tape, and optical storage. SAN solutions often use a dedicated network behind the servers, based primarily on fiber-channel architecture. Fiber channel provides a highly scalable bandwidth over long distances with the ability to offer full redundancy, high availability, and high performance. A SAN normally supports direct high-speed transfers between servers and storage devices in the following ways:

- *Server to storage*: This is the common method of interaction with storage devices. The SAN advantage is that the same storage device may be accessed serially or concurrently by multiple servers.

Figure 2: Storage area network (SAN) reference architecture

- *Server to server:* In this case, a SAN is used to enable high-speed and high-volume communications between servers.
- *Storage to storage:* With this configuration, a disk array could back up its data directly to tape across the SAN without processor intervention. Alternatively, a device could be mirrored remotely across the SAN.

Figure 2 shows the typical SAN architecture.

However, even SANs do not come without problems and limitations. For instance, network managers are often concerned with interoperability because vendors have designed proprietary products to maintain a competitive advantage. Despite the promise of interoperability, there are no standards for a heterogeneous storage environment, and this on the one side introduces restrictions in the technology choice, while on the other it often leads to less-than-optimal solutions, either for functionalities or for costs. Other factors that affect interoperability of SANs are related to the difficulty in making use of efficient management software and diagnostic tools. Some of the main vendors, like IBM and HP, are offering complete SAN frameworks, in which the storage technology is integrated with management and diagnostic tools provided by the vendor. However, these solutions often look like the one-size-fits-all solutions that we previously mentioned, most of the time tailored for large network infrastructures, difficult if not impossible to integrate with existing technologies, limited to a single family line of products and one single vendor, and usually extremely expensive.

SAN Security Issues

Another issue that is often disregarded when SANs are deployed is security (Rhodes 2005). As Haron (2002) points out, since SAN is usually used in highly critical systems that require high availability, confidentiality, and integrity, organizations must be aware of all potential points at which a security breach might occur and include these considerations when designing SAN security solutions.

In other terms, this observation means that all the usual security problems, risks, threats, and countermeasures apply to SANs too, despite the fact that the adoption of consolidated security solutions is still not so common in the BCP field.

In addition to security considerations based on the networked nature of SANs and the value of information usually transmitted on SAN infrastructures, laws such as the Sarbanes-Oxley Act of 2002 and the Health Insurance Portability and Accountability Act of 1996 (HIPAA)—to name the main U.S. related laws; similar laws have been promulgated in the European Union and in other countries—make an organization accountable for how information is processed and stored.

Threats to SANs can be summarized in three basic categories:

- *Unintentional and due to accidents or mistakes:* These are what we have called small disasters, which can happen often, may have limited consequences when considered singularly, but may become one of the most serious causes of down time because of their frequency. Precautions must be taken as for all critical network components. For instance, SAN switches have ports that can be restricted to management purposes only. Next, the physical access to the SAN can be restricted by configuring dedicated management networks—a common design choice in modern network layouts. Access to the management network can be controlled by means of corporate firewalls and virtual private networks. Finally, access control lists at the application level should be used to authenticate and authorize users accessing the SAN configuration. In short, all common solutions for the correct management of a critical IT asset, as a SAN is, should be put in place. Finally, encryption for both data in transit and data kept in storage must be used.
- *Simple malicious attack that uses existing equipment and possibly some easily obtained information:* These attacks usually come from internal sources, such as disgruntled employees looking to destroy information or someone looking to gain profit or an advantage from the information obtained. Security measures applied to address the previous point are effective here too, but often are not sufficient. There are numerous ways an internal source can obtain sensitive information under false pretenses—the main one is posing as an authorized user or device—and could result in gaining access to the SAN. To counter these risks, authentication requirements should apply to users, to the devices, and to applications. However, although authentication is the main mechanism for preventing the impersonation of other identities, it has limitations, mostly related to the quality of the implementation and the strength of credentials. If the credentials are weak, or if authentication data are exposed because of faulty implementation, the mechanism itself can and will be defeated. For these reasons, architectural countermeasures are normally adopted. These rely on the fact that the networked architecture must be designed to minimize the possibility of spreading an intrusion into the network. The basic means to achieve this goal is zoning, which is a method of arranging SAN devices into logical groups over the physical configuration

of the fabric. Zoning adds another level of security to a SAN because it controls access to a SAN from a host device. Only devices that are authorized to access a particular storage resource are allowed to do so.

- *Large-scale attack on SAN infrastructures:* Although attacks of this type have been extremely rare in SANs today, with the increasingly diffusion of SANs and the augmented value of information traversing and stored on SANs, it is likely that even SANs will become targets of external attacks, as many of the network components of an IT infrastructure currently are. Solutions to be applied are the ones studied and adopted to protect large and complex IT networks. SANs must be considered as other critical assets, just as corporate databases or application servers. This is a strong reason for a better and enlarged convergence between BCP and security planning.

Internet SCSI

An alternative, and more recent (Satran et al. 2004), SAN protocol is iSCSI, which uses the same SCSI command set over TCP/IP (and, typically, Ethernet). In this case, the switches are Ethernet switches and the network is not referred to as a fabric. The iSCSI protocol uses TCP/IP for its data transfer. Unlike other network storage protocols, such as fibre channel (which is the foundation of most SANs), it requires only the simple and ubiquitous Ethernet interface (or any other TCP/IP-capable network) to operate. This enables low-cost centralization of storage without all of the expense and incompatibility normally associated with fibre-channel storage area networks. The other benefit that iSCSI promises to bring is a lower implementation and management complexity with respect to fiber-channel SANs.

However, again, as already seen for other emergent technologies, the early hype faded and problems emerged to slow down the adoption. Critics noted that one misguided expectation about iSCSI was that it could be the SAN protocol that would quickly replace fiber channel. This did not happen, and vendors, such as IBM, that initially targeted the same market segment of fiber-channel SAN, have modified their offering of iSCSI solutions from big high-end premium products to entry-level storage devices for mid-sized businesses. According to these indications, iSCSI seems to find its place as a solution aimed at those companies that could not afford the enormous costs of high-end fiber-channel SANs. There are actually signs that the shift of iSCSI from a competitor of fiber-channel SAN to a complementary solution able to lower the entry barrier has been the right move. IDC, a leading provider of global IT research and advice, has forecast that by 2009, over 30 percent of all SAN disk storage systems revenue and almost 50 percent of SAN revenue in price bands 1 to 4 (systems with average selling price of \$1 to \$49,900) will be generated from storage systems based on iSCSI technology. From 2004 to 2009, the iSCSI SAN market will grow at a compound annual growth rate of 107 percent. If this trend is confirmed, it can be welcomed as an efficient, sophisticated, and reasonably priced SAN solution for mid-sized enterprises that have so far been excluded from adopting SAN technology.

TRAINING AND TESTING

Business Continuity Training

Operational continuity, emergency response, and security plans should be exercised twice a year. For example, many companies, such as Texas Instruments and Hewlett Packard, operate out of their backup data centers periodically, so that security experts are prepared for any disasters that may hamper normal business operations. Updated plans alone are not enough to ensure continuity if recovery team members do not exercise them and therefore do not know exactly what they are supposed to do. Team members should receive training in recovery concepts in general and their team's functions in particular. This way, needed improvements in strategies and plans are discovered, and team members may acquire valuable experience in dealing with their duties in the event of a recovery scenario.

An organization should review the following plan elements during the exercise:

- *Recovery team alert list:* Commonly known as a "calling tree," this is contact information for all personnel assigned to the team. Because this list can change frequently, team leaders should update it regularly and communicate changes to each team member.
- *Critical functions list:* This is a list of critical functions that each team must accomplish in a recovery scenario.
- *Team recovery steps:* Strategies for recovery of critical functions must be reviewed to ensure that they meet the objectives stated in the BIA.
- *Functional recovery steps:* Procedures to complete all operational recoveries must be reviewed and validated to determine effectiveness and efficiency.
- *Vendor and customer list:* This contact information for critical vendors and customers must be reviewed to determine its accuracy and completeness.
- *Offsite storage list:* Critical facilities or resources stored offsite must be reviewed to determine their operational status and completeness.

Testing Processes and Procedures

To determine which business processes to test and in which order, the BIA analysis should be at hand, because it is the BIA that states mission-critical activities and defines recovery requirements, such as the RTO and RPO. The most challenging aspect of exercising and testing a BCM plan is devising a testing method and implementation schedule such that the following occur:

- The BCM and DR plans are tested to the fullest extent possible, according to the BIA.
- The costs are sustainable and well documented.
- Interruptions of normal business operations are minimal or nonexistent.
- The tests provide a high degree of assurance in recovery capability.
- Evaluation of test results provide quality feedback for maintaining BCM and DR plans.

One of the most common methods for testing BCM and DR plans involves using checklists, performing simulations, tabletop exercises, checking the procedures in parallel between the main and an alternate site, and fully testing the DR plan by interrupting operations.

Checklist Testing

Checklists are the primary tools for testing a plan, because they are inexpensive to implement and maintain. A checklist should be subdivided into groups of checklists dedicated to the different business units or organization areas involved in the DR plan. They should be specific and appropriate for each business unit and for the phases of mission-critical activities in which they are involved. In addition, the experience of each business unit should be used in preparing and updating checklists. A checklist test can be used to validate multiple components of the DR plan; for example, key procedures validation, hardware and software configuration, documentation completeness and update status, availability of process-specific resources, and data backup correctness and reliability.

Simulation Testing

The purpose of simulating a failure is to evaluate the effectiveness of the BCM plan without interfering with normal business operations. Hardware, software, personnel, communications, procedures, documentation, transportation, utilities, and alternate site processing should be included in a simulation test. Factors such as traveling, moving equipment, or coordinating activities with external agencies may not be feasible during a simulated test. However, checklists can provide a reasonable level of assurance for many of these scenarios.

Tabletop Exercise

According to the Disaster Recovery Institute International (DRII), a tabletop exercise is “one method of exercising teams in which participants review and discuss the actions they would take per their plans, but do not perform any of these actions. The exercise can be conducted with a single team, or multiple teams, typically under the guidance of exercise facilitators.” A tabletop exercise is a convenient way of testing a BCM plan; however, to be effective, it requires careful planning. First, the BCP or BCP sections that are to be tested must be identified. Then, members of the recovery team, those responsible for business processes whose BCP will be exercised and observers (e.g., senior managers, auditors, etc.) are called to participate. The tabletop exercise must then be focused on one or two disruption scenarios, such as failures to support services, to the IT infrastructure, or to key software applications (Hayes 2000).

Parallel Testing

In parallel tests, historical transactions, such as the prior business day's transactions, are processed against the preceding day's backup files at the replicated or hot site. All reports produced at the alternate site should agree with those produced at the main site.

Full-Interruption Testing

A full-interruption test activates the DR plan in its entirety. It is clearly the most meaningful test and also the

most expensive and intrusive. It could disrupt normal operations and result in losses to the company.

BUSINESS CONTINUITY LAWS AND REGULATIONS

The matter of BCM has been the subject of several laws and regulations in the past decade. Such laws and regulations are often specific to an industry sector, and specify requirements for business continuity and disaster recovery planning. Requirements vary among industry sectors, although they all seem to be inspired by general best practices and guidelines—similar to the ones described in this chapter—developed over the past decade. The bottom line for all these laws and regulations is to force organizations to exercise due care to ensure that necessary data are available. Noakes-Fry, Baum, and Runyon (2005) presented a comprehensive list of BCM/DR related laws and regulation for the four key industry sectors: health care, government, finance, and utilities. Table 1 lists the main U.S. laws and regulations.

BUSINESS CONTINUITY AND INVESTMENT DECISIONS

BCM and DR solutions are usually expensive. For comprehensive solutions, costs were high in the old days of data centers and continue to be high today in the world of networked resources, replicated servers, and mirrored sites. A review by Toigo (2004) in *Network Computing* presented solutions from some vendors that address the needs of a reference fictional retailer taken as the test case. Costs for those solutions began at approximately \$300,000, rose to \$700,000, surpassed \$1 million, and reached \$6 million for the most expensive. Indeed, business continuity is not compatible with low budgets, especially because by its nature business continuity is organization-wide and not modular.

Widup (2003) raises an interesting question in her SANS Institute GSEC Practical: because economic difficulties have severely affected the development of BCM plans, why is BCM still proposed as an organization-wide plan instead of developing less monolithic and more modular approaches and less comprehensive and more affordable projects to comply with reduced investments? This is more a business than a technical trade-off that is rarely addressed in the BCM literature and online publications. Often statistics are presented about the percentage of companies that do not have any kind of BCM plan in place, do not perform any kind of testing and maintenance of plans, or do not invest in BCM planning. This is evidence that the perceived importance of BCM has diminished rather than increased. For instance, Widup (2003) discussed the results of a poll conducted by *InformationWeek* (D'Antoni 2003), that of the 300 business technology executives interviewed about their 2003 budget plans and IT strategies, 65 percent said that BCM planning and improved disaster preparedness are priorities. This is a decrease from 77 percent the previous year. Moreover, some 61 percent of executives at small companies reported a continued commitment to

Table 1: BCM/DR-Related Laws and Regulations

Industry Sector	Laws and Regulations	Requirements for BCM
Health care	Health Insurance Portability and Accountability Act (HIPAA) of 1996	Requires data backup plan, DR plan, and emergency-mode operation plan, as well as appropriate measures relative to the size, complexity, and resources of the organization.
	Food and Drug Administration (FDA) Code of Federal Regulations (CFR), Title XXI, 1999	Requires electronic records and electronic signatures.
Government	Federal Information Security Act (FISMA) of 2002, Title III of the E-Government Act of 2002 (PL 107-347, December 2002)	Mostly focused on data security rather than BCM/DR.
	Continuity of Operations (COOP) and Continuity of Government (COG). Federal Preparedness Circular 69, July 26, 1999	Requires planning considerations for federal government operations. BCP must be implemented even without warning and operational no more than 12 hours after activation, and sustainable for up to 30 days.
	National Institute of Standards and Technology (NIST) Special Publication (SP) 800-34, <i>Contingency Planning Guide for Information Technology Systems</i> , 2002	Specifies detailed recommendations from NIST, requiring contingency, DR, and COOP plans.
	NIST 800-53, Recommended Security Controls for Federal Information Systems, February 2005	Provides guidelines and requirements for BC planning policy and procedures, plan, training, plan testing, and updating.
Finance	Federal Financial Institutions Examination Council (FFIEC) Handbook, 2003–2004 (Chapter 10)	Requires managers to be accountable for organization-wide contingency planning and for timely resumption of operations in the event of a disaster.
	Basel II, Basel Committee on Banking Supervision, <i>Sound Practices for Management and Supervision</i> , 2003	Requires banks to put in place BC and DR plans to ensure continuous operation and to limit losses.
	Interagency Paper on Sound Practices to Strengthen the Resilience of the U.S. Financial System, 2003	Focused on systemic risk as a result of the World Trade Center disaster. Requires BCPs to be upgraded and tested to incorporate new risk categories. Authorizes actions against banks that fail to comply with specified requirements.
Utilities	Governmental Accounting Standards Board (GASB) Statement No. 34, June 1999	Requires a BCP to ensure that an agency's mission continues in a time of crisis. Applies to all government entities that operate utilities.
	North American Electric Reliability Council (NERC) Cyber Security Standards, 2006	Formerly NERC 1300, replaces NERC 1200. Defines mandatory obligations for recovery plans.
	Federal Energy Regulatory Commission (FERC) RM01-12-00 (Appendix G), 2003	Mandates recovery plans. Does not apply to Rural Utilities Service (RUS) borrowers and limited distribution cooperatives.
	RUS 7 CFR Part 1730, 2005	Emergency restoration plan required as condition of continued borrowing. Applies to all rural <i>utility</i> borrowers.
	Telecommunications Act of 1996, Section 256, Coordination for Interconnectivity	Requires the Federal Communications Commission (FCC) to establish procedures to oversee coordinated network planning by carriers and other providers.

BCM planning, a drop of 14 percent compared with the year before. Responses among managers at mid-sized companies showed a similar decline, and larger sites were down 7 percent from the previous year.

Given the costs presented in Toigo (2004) and the current economic difficulties, it is no surprise that small and mid-sized companies have severely cut spending on BCM plans. Nevertheless, the BCM field seems to have no adequate proposal to face this situation. This demonstrates a weakness of BCM planning, which has made it very difficult to formulate proposals well suited for small and mid-sized companies, which often simply rely on basic tape-based backups and other low-cost precautions.

One way to make BCM solutions more attractive to small and mid-sized companies is to make them more modular; for example, there should be different modules for different business functions, instead of imposing an organization-wide approach. Modular solutions are easier to integrate with existing infrastructures and technology. Most of the expense of BCM solutions comes from the purchase of dedicated equipment, substitution of existing technology/components, and the impossibility of preserving previous IT investments that often cannot be integrated or reused with BCM solutions. Moreover, initial expenditures are not the only barrier to adopting BCM solutions. If those solutions are not made less expensive to maintain and update, the natural consequence of each period of economic difficulty will be the reduction of investments in BCM and in the maintenance and development of existing plans. Floods, fire, and power outages become secondary thoughts, and BCM budgets get smaller. We should admit openly that from a risk-management perspective it does make sense.

However, it is clear that modularizing a BCM plan and supporting only some functions instead of *all* mission-critical functions means having plans that are generally inadequate to sustain business continuity in the event of severe disasters. The coherence of an enterprise-wide plan, based on enterprise-wide analyses, developments, and tests, would be lost, as well as the performance and effectiveness of the more sophisticated technology in place today that is able to satisfy continuous-availability requirements. Nevertheless, BCM analysts should consider that in most cases, cutting expenditures on BCM is not merely done because of the shortsightedness of a company's management; instead it may be the result of a realistic calculation in situations in which financial shortages are the primary reason why a company goes out of business.

In these situations, BCM analysts and vendors should make efforts to demonstrate the cost-effectiveness of solutions, to consider the trade-off between BCM investments and other technologies from the perspective of corporate management, and to be able to scale down solutions when circumstances need it.

Finally, to foster the adoption of complex BCM solutions, some BCM literature, especially online literature and marketing communications, seems sometimes to stress excessively the potential consequences of catastrophic and tragic events on business. Unfortunately, these consequences are sometimes presented without a corresponding realistic analysis of the likelihood of occurrence of those events, which actually is extremely low

for the great majority of organizations. This literature has much in common with many marketing campaigns about cyberattacks in the information security area: both tend to focus on short-term emotional reactions instead of demonstrating cost-effectiveness and the technical soundness of solutions. Information to enable a correct cost-benefit analysis is not provided to the customers, which turns out to be a shortsighted strategy in the mid- to long-term period when economic considerations become paramount for investment decisions.

BEYOND BUSINESS CONTINUITY: BUSINESS RESILIENCE

The world of business continuity is a lively world, indeed. We have just moved from disaster recovery to business continuity management, considerably enlarging the scope of the discipline, and many are already calling for a new step ahead (critics would say that yet another buzzword is taking the scene). Business resilience (BR) is the new goal. Before introducing a definition, we cannot avoid observing that literally, *resilience* means "an ability to recover from or adjust easily to misfortune or change" (from the *Merriam-Webster Dictionary*), which looks exactly like what we have discussed in BCM. Apparently, critics are not without their arguments. However, the notion of BR is the topic of many new publications in the BCM field (Cocchiara 2005; Owens 2004; Ross 2004) and has been emphasized in the last BCM (Business Continuity Management) World 2005 Conference, whose Web page (www.bcmworld.net/conference.htm) states: "Business resilience [can be defined] as the ability of an organization's business operations to rapidly adapt and respond to internal and external dynamic changes and continue operations with limited impact to business." It is hard to distinguish BR from BC reading this definition, but luckily the same Web page specifies that "Business Continuity has evolved over the years, taking shape under the influence of many parts including IT disaster recovery (DR), contingency planning, crisis and emergency management to name a few. Today, the scope of business and continuity management has broadened in discipline to encompass 'Business Resilience.' Business resilience moves us forward along the continuum of business continuity planning from the sense of reacting to recover from an event to becoming immune to the event." Thus, BR is about assuming an aggressive, offensive posture toward events that may impair business operations, in contrast to the defensive approach assumed so far.

Although the definition still seems a little too vague to be operational, some consequences can be derived. An "offensive posture" translates into more planning, more organization, and more readiness. If an organization wants to become immune to events that may provoke failures, then mitigation and recovery strategies are no longer the focus of the process because the goal shifts from deploying the fastest and most effective recovery strategies to organizing the whole business and infrastructure to not require any recovery at all. The change in the perspective could be enormous, as well as the efforts and investments required to achieve it. That is probably even the best argument for critics: whether achieving a real business resilience will

require such an amount of work, time, and money, it is likely that very few will be able to do that, while for the great majority, business resilience will simply turn into the new buzzword used in revamping old solutions.

Principles of Business Resilience

A better definition of BR's goal can be found in Owens (2004). Key to BR seems to be that it is not just about surviving a disaster or recovery from a failure. The perspective is larger than that because at the core, BR is about the ability to deal with sudden change. It is impossible to account for and prepare for every possible eventuality, of course; it is nevertheless possible to design for resilience and to train for dealing with disruption. Thus, BR is about dealing with sudden change, which may or may not be negative or destructive change. They could be positive changes, as well, such as technological improvements, reorganizations, and so forth. This represents the enlarged perspective and the most challenging goal, because ultimately BR represents a shift from the traditional field of disaster recovery and business continuity, which are about system failures and business losses, to change management, agile organizations, and preparedness in a dynamic context.

Ingredients proposed for an effective BR stem from efficient communication and collaboration among people, strict dependency from the "weakest link" (i.e., the weakest component in the organization is likely to provoke the failure), profound knowledge and in-depth analysis of the context in which a business is operated (this because failures most of the time do not happen randomly), actual measures of key factors (characteristics such as the availability of a critical system must be measured with precise metrics, not by means of gross, subjective estimates), and interchangeability of infrastructural components. Finally, BR must be an approach, so training is of fundamental importance.

A Business Resilience Framework

IBM, for example, has proposed a framework for BR that includes five major attribute classes associated with improved business resilience:

- *Control and comply*: the attributes necessary to anticipate, evaluate, and control risks associated with complying with industry and government regulations, as well as those risks associated with environmental, social, technical, and economic factors
- *Predict and detect*: the attributes necessary to predict, detect, estimate, measure, and report events to ensure security, privacy, and protection of critical data, enabling the business to respond to any threats that may jeopardize business operations
- *Deflect and solidify*: the attributes necessary to create a solid physical and logical topology to deflect problems and ensure continuity of operations through reliability, redundancy, and failover
- *Adapt and optimize*: the attributes necessary to ensure adaptable, efficient, and flexible integrated risk-mitigation strategies, technologies, and processes

- *Protect and preserve*: the attributes necessary to ensure that the business is preserved and protected against accidental and intentional damage, alteration, or misuse.

Together with the five attribute classes, the IBM framework identifies six object layers related to the business resilience. Those layers model the corresponding layers of most business organizations. They are:

- *Strategy*: objects related to the strategies used by the business to complete day-to-day activities while ensuring continuous operations, such as financial, manufacturing, and disaster recovery strategies
- *Organization*: objects related to the structure, skills, communications, and responsibilities of your employees (Examples include human resources, training, and internal and external communications.)
- *Applications and data*: objects related to the software necessary to enable business operations, as well as the method used to develop that software (Examples include customer relationship management (CRM) applications, enterprise resource planning (ERP) applications, databases, and transaction processors.)
- *Processes*: objects related to the critical business processes necessary to run the business, as well as the IT processes used to ensure smooth operations (Examples include accounts receivable, accounts payable, change management, and problem management.)
- *Technology*: objects related to the systems, network, and industry-specific technology necessary to enable your applications and data (Examples include host systems, workstations, and IP networks.)
- *Facilities*: objects related to the buildings, factories, and offices necessary to house your organization and your production or service technologies (Examples include data centers, office buildings, and physical security operations.)

IBM uses its business resilience framework as a logical representation that provides an examination of a business that is both comprehensive and modular. The six object layers expand into more than 140 objects examined by means of the five attribute classes for a complete analysis of resilience capabilities.

It must be noted, however, that the framework for BR has many similarities with traditional risk management and BC/DR plans. For instance, considering the attribute classes, "Control and comply" are issues that a risk analysis takes into account, as well as "Predict and detect," which is partially covered by a BIA, too. Next, "Deflect and solidify" looks like a different way to name recovery solutions. Considering the six object layers, instead, it is evident that they identify subjects that have always been considered in BCM.

In this regard, it seems that criticisms concerning the difficulty of clearly identifying the innovative nature of BR are confirmed.

CONCLUSION

Internet connections have driven the development of new business models that have enlarged and modified the

scope of DR since the days of mainframe-based data centers. This amplified discipline has taken the name of *business continuity management*, of which DR is today one aspect of a greater process aimed at ensuring the continuity of mission-critical business activities. A requirement that follows this evolution in business models is the need for immediate recovery and continuous operations with zero down time as their ultimate goal. Although the zero-down-time goal is still extremely difficult to achieve, and this should be stated clearly in each BCM project, the BCM field has developed new planning methods and techniques to match these requirements. As a consequence, the process of putting in place an effective BCM plan uses sophisticated technologies, but the many interconnections with both the IT infrastructure and the business functions of a company make it more complex. Companies could suffer severe losses if they experience one of the many risks, not just traditional disasters, but even so-called small disasters, which include failures of the IT infrastructure, telecommunications, power outages, and human errors. E-commerce business models can no longer sustain those frequent downtimes or network outages as in the past, when companies accepted RTOs of some days in the event of an IT failure and RPOs that restored resources to the previous status.

Processes that enable a more efficient recovery phase in the event of a disaster, such as the business impact analysis, the work area recovery, risk analysis, and the innovative backup and recovery techniques, therefore assume great importance.

GLOSSARY

Activation: The implementation of business continuity procedures, activities, and plans in response to an emergency, disaster, or incident.

Alternate Site: A location, other than the normal facility, used to process data and conduct critical business functions in the event of a disaster.

Backup: The process of copying data (paper-based or electronic) so as to make the data available for use if the original data are lost, destroyed, or corrupted.

Business Continuity Management (BCM): A management process that identifies potential impacts that threaten an organization and provides a framework for ensuring the continuity of business operations in the event of a disaster, failure, or unplanned incident.

Business Continuity Plan: A clearly and formally defined plan to use in the event of an emergency, incident, or failure. Typically, it includes the description of all key personnel, resources, services, and actions required to manage a BCM process.

Business Continuity Planning: The process of planning for the identification of potential losses, prevention measures, viable recovery strategies, and training/testing/maintenance activities provided by the BCM process.

Business Impact Analysis (BIA): The management analysis that addresses financial and nonfinancial effects that might result in the event of a disaster or failure. The BIA represents the basis for every BCM strategy and solution.

Data Mirroring: A process that permits the copying of data instantaneously to another location.

Disaster: Any event that can cause an organization to be unable to provide critical business functions for a certain period of time. Also commonly known as a *Disruption*.

Disaster Recovery: An integral part of the BCM plan aimed at recovering and restoring an organization's capabilities (e.g., IT and telecommunications) after a disaster.

Electronic Vaulting: Transfer of data to an off-site storage facility via a communication link or a different portable medium.

Facility: Location containing equipment and infrastructure to perform normal business functions.

Loss: The financial or nonfinancial consequence resulting from a disaster/failure.

Mission-Critical Activities: The critical operational or business activities necessary to the organization's ability to achieve its business objectives.

Network Outage: The interruption of system availability as a result of a communication failure affecting a network.

Offsite Storage Facility: A secure and remote location where backups of hardware, software, data files, documents, or equipment are stored.

Risk Assessment: The overall process of risk identification, analysis, and evaluation.

Risk Management: The processes and structures put in place to effectively manage negative events to minimize adverse effects and reduce damages or losses to an acceptable level.

Service-Level Agreement (SLA): A formal agreement between a service provider and the client that specifies all conditions of service provision.

System Outage: An unplanned interruption in system availability resulting from operational problems or hardware/software failures.

Work Area Recovery: The identification of the minimum level of resources (e.g., personnel, hardware, software, data, or telecommunications) required after a failure that permits an organization to conduct its mission-critical activities at a minimum level of service.

INTRODUCTION

Surveys highlight for employers the importance of having a well-drafted e-mail and Internet use policy. These surveys show that the majority of employers adopt e-mail and Internet use policies for important business reasons that range from addressing employee productivity to preventing hostile work environments. For example, the American Management Association's *Electronic Monitoring & Surveillance Survey* (2005) (hereafter referred to as the 2005 AMA Survey) reported that 84 percent of the organizations in their survey had written policies concerning personal e-mail use and 81 percent had written policies concerning personal Internet use. Although less common, organizations also reported they had written policies covering personal instant messenger (IM) use (42 percent), operation of personal Web sites on company time (34 percent), personal postings on corporate blogs (23 percent), operation of personal blogs on company time (20 percent), and use of cell phones in the office (27 percent).

In its 2003 *E-Mail Rules, Policies and Practices Survey* (hereafter referred to as the 2003 AMA Survey), the American Management Association reported that more than one third of respondents had experienced problems related to their e-mail systems, including having their computer systems disabled for a time, having their businesses interrupted for a time, and having computer viruses enter their systems through e-mail. Other surveys have demonstrated that employees' misuse of Internet access may also be a serious business concern for employers. It has been reported that many employees use the Internet at work for nonbusiness reasons such as viewing pornography, analyzing their investment portfolios, making personal travel arrangements, locating friends, following sports teams, and shopping for merchandise (Burgunder 2004). Clearly the use of e-mail and Internet access by employees in the workplace calls for well-designed e-mail and Internet policies to prevent abuse of work time and to minimize other business and legal risks.

Although there are valid business reasons for employers to carefully craft e-mail and Internet use policies to avert abuses by some employees, it is likely that the vast majority of employees do not engage in misconduct or abuse the privilege of using the employers' communications equipment. Furthermore, employers benefit from employees' enhanced productivity made possible by e-mail and Internet access in the workplace. In addition, employees have legal rights related to the workplace that need to be considered when employers draft e-mail and Internet use policies. This chapter endeavors to help employers draft and enforce e-mail and Internet use policies that achieve an appropriate balance between preventing abuses and protecting employees' rights in the workplace.

PURPOSE AND FUNCTION OF E-MAIL AND INTERNET USE POLICIES

An employer's policy covering e-mail and Internet use is a key workplace management tool. When the policy is properly drafted, effectively communicated to employees, and consistently enforced, it enables the employer to establish guidelines for acceptable and unacceptable

workplace behavior involving the use of e-mail and Internet access (Page 2002). An employer's e-mail and Internet access policy should notify employees of acceptable and unacceptable workplace behavior (Page 2002). Another advantage of an effective policy is that it may prevent losses to the employer that may result from employees deliberately or carelessly misusing e-mail and Internet access. These losses may include misappropriations of intellectual property and employer liability for civil damages or criminal sanctions. An effective e-mail and Internet use policy helps an employer achieve legal compliance with myriad workplace laws that protect employees' rights and restrict the employer's and employees' actions related to e-mail and Internet systems, provided the employer follows the policy, applies it fairly, and trains its managers on implementation of the policy (Harmon 1982, 23). Finally, an effective e-mail and Internet use policy reserves the employer's property and management rights, including the right to monitor the employer's equipment and systems for a variety of business reasons and the right to discipline or terminate employees for violating the policy (Harper Business 1990, 340–2). See Table 1 for a description of important policy issues and drafting suggestions.

Table 1: Drafting E-Mail and Internet Use Policies

Important Policy Issues	Drafting Suggestions
Establishing the purpose of providing employee use of company-provided e-mail and Internet access	Company-provided e-mail and Internet access and related systems and equipment are provided to employees for the purpose of conducting company business.
Defining the scope of the e-mail and Internet use policy broadly	This policy covers e-mail access and the contents of e-mail messages, Internet or intranet communications, records of Internet or intranet access, and other electronic communications, files, and data of any kind stored or transmitted by or on company-owned or leased systems or equipment. The policy covers wireless access to the company's equipment and systems. It also covers remote access to company systems and equipment.
Establishing company ownership of electronic communications, files, and data	Electronic communications, files, and data covered by this policy remain company property even when transferred to equipment that is not owned by the company.
Clarifying that employees have no expectation of privacy in their use of company-provided e-mail or Internet access and that all information communicated on the company's systems is company property	Employees should <i>not</i> consider any communications made using company-provided e-mail or Internet access to be private, even if those communications are personal in nature. Except as provided by law, all information communicated on any of the company's systems or equipment, including e-mail or use of Internet access, is company property.
Establishing a standard for employees' use of company-provided e-mail and Internet access	Employees are authorized to use e-mail and Internet access for company work-related purposes and consistent with company policies and procedures. Employees are expected to use good judgment and act courteously and professionally when using company-provided e-mail and Internet access.
Permitting employees to make reasonable personal use of company-provided e-mail and Internet access while protecting company business interests	Employees may make reasonable personal use of company-provided e-mail and Internet access so long as the use does not interfere with the work duties of any employee, violate company policy, or unduly burden the company's equipment or systems, and does not undermine the company's business interests.

(continued)

Table 1: (Continued)

Important Policy Issues	Drafting Suggestions
	The permission to make reasonable personal use of company-provided e-mail and Internet systems may be revoked or revised at any time.
Prohibiting employees from using company-provided e-mail and Internet access for unlawful reasons	Employees may not use company-provided e-mail and Internet access for any illegal purpose. Uses that are illegal include violating copyright or trade secret laws; spam laws; child pornography laws; antitrust laws; laws restricting exports of information or other products for national security reasons; laws prohibiting online gambling, etc. Unauthorized installation of adware or spyware on another's computer, unauthorized access of another's computer, and improper acquisition, use, or disclosure of personally identifying information related to customers, employees, or other persons may also be unlawful and/or in violation of company policy. Be aware of special restrictions on access, use, or disclosure of personally identifying information related to children, especially those under 13 years of age.
Requiring employees to follow security procedures regarding use of e-mail and Internet access	Employees must follow security procedures established by the company related to the use of company-provided information systems and equipment including e-mail and Internet access. No person shall use any other user's identification or password or attempt to bypass security features to access information that the person is not authorized to access.
Prohibiting employees from using company-provided e-mail and Internet access for reasons that violate company policy	Employees may not use company-provided e-mail and Internet access for any reason that violates company policy. Company policy prohibits viewing, storing, or distributing pornography, sexually offensive materials, or other materials inappropriate for the workplace. It is also a violation of company policy to make or distribute harassing or discriminatory communications related to sex, gender, race, religion, national origin, age, or disability. In all communications, including e-mail and Internet chat, employees must follow company policies regarding improper disclosures of trade secrets and confidential or proprietary information.
Requiring employees who make electronic communications about the company or work-related matters in blogs, Internet chat rooms, instant messages, or by e-mail, etc. to clarify the personal nature of their comments and not to disclose confidential company information	Employees must exercise caution and protect company interests in all communications they make with persons outside the company that are made outside their job responsibilities (personal communications). For example, employees who participate in instant messaging, e-mails, Internet chats, and blog postings, etc. must state that any opinions expressed in such communications about work-related matters are the employees' own and have not been reviewed or approved by the company. In such communications, employees are prohibited from disclosing company trade secrets and confidential or proprietary information of the company. Employees may not disclose insider information that may violate securities laws and regulations. Employees may not post copyrighted material in such communications without authorization of the copyright holder, and should be aware that doing so may lead to civil and criminal penalties. Company logos and trademarks may not be reproduced within employees' personal communications as described above. In addition, employees should be respectful in their communications with persons outside the company and must consider the impact of their statements on others including the company, its products, company managers and supervisors, the employees' coworkers, and the company's competitors. Employees' communications are subject to these rules even if the employee uses no company-provided equipment and is not communicating on company time.

(continued)

Table 1: (Continued)

Important Policy Issues	Drafting Suggestions
Prohibiting employees from sending mass e-mail for personal reasons that may burden the company's information technology systems	Employees may not send spam or other mass e-mails for personal reasons that are not related to their work. A mass e-mail is a message sent simultaneously to more than _____ recipients (enter employer's threshold, e.g., 50).
Reserving the company's right to access or to retrieve communications, files, and other electronic data, use of computer forensics, or use of blocking software	The company may access, monitor, intercept, block access, inspect, copy, disclose, use, destroy, delete, recover using computer forensics or other techniques, and/or retain any communications, files, or other data covered by this policy, except as required by law. Such company actions may occur at any time and with no advance notice. Employees are required to provide passwords requested by the company to enable access to company property.
Anticipating the company's obligations to respond to government requests for electronic communications and other documents	The company may access, monitor, intercept, and/or disclose communications, files, or other data covered by this policy in relation to government investigations for national security or law enforcement purposes, without further notice.
Reserving the company's right to discipline or terminate employees for violations of the e-mail and Internet use policy.	Violations of this policy may result in immediate termination of employment or other discipline that the company determines is appropriate under the circumstances.
Reserving the right to take action against company contractors whose employees violate this policy	This policy applies to the employees of contractors who are authorized by the company to use company-provided e-mail and Internet access. Contractors are responsible for ensuring compliance with this policy by their employees. The company reserves the right to exclude contractor's employees who violate this policy from further dealings with the company.

Note: This table has been prepared from the perspective of a private-sector, nonunion employer in the United States that employs at-will employees, referred to here as "the company." The information in the table does not provide legal advice for policy drafters. All workplace policies should be reviewed by the organization's legal counsel.

BALANCING BUSINESSES' NEEDS AND EMPLOYEES' PRIVACY RIGHTS

A well-drafted policy serves as a legal compliance mechanism for management, such that following the policy will avoid violating laws that protect employee rights. A well-drafted policy will be enforceable legally because it will at least provide the minimum protection for an employee that is required by a multitude of laws regulating the employment relationship. Today, one of the greatest challenges for employers is to draft an e-mail and Internet use policy that balances the business's needs with employees' privacy rights consistent with applicable privacy and data protection laws. Given the different regulatory approaches for workplace privacy and data protection, this is not an easy task.

The Global Perspective

When drafting e-mail and Internet use policies, employers with employees outside the United States need to be aware of privacy and data protection laws in other countries that may be far more protective of employees' rights than U.S. laws. For example, in the twenty-seven member countries of the European Union, privacy and data protection are considered to be fundamental rights of individuals (Lasprogata, King, and Pillay 2004). These countries have laws that afford individuals residing in these countries

significantly heightened privacy and data protection rights. In addition, even if a company has only U.S. employees, multinational companies need to be aware that the same privacy and data protection laws may apply to customer communications and restrict the company's ability to collect, use, or disclose personally identifying information about their international customers.

Europe has a long history of treating personal privacy as a fundamental right. As Article 8 of the European Convention for the Protection of Human Rights and Fundamental Freedoms (1950) (ECHR) provides: "Everyone has the right to respect for his private and family life, his home and his correspondence." The Treaty of the European Union recognizes the ECHR and requires members of the European Union to respect the fundamental rights guaranteed by the Convention (Treaty Establishing the European Community 1992). Electronic communications are a form of personal correspondence. For example, people in Europe have fundamental rights to privacy in their e-mail communications, even when the communications are made using the employer's e-mail system (*Halford v. United Kingdom* 1997).

More recently, personal data protection has also been recognized as separate but related fundamental right in the European Union. The Charter of Fundamental Rights of the European Union (2000) (EU Charter 2000) provides: "Everyone has the right to the protection of personal data concerning him or her." Further, the European Union's

Data Protection Directive (Directive 95/46/EC 1995) requires EU member states to adopt data protection legislation regulating the processing of personal data and the free movement of such data (Directive 95/46/EC 1995). The Data Protection Directive expressly refers to the fundamental rights of privacy that are contained in the above-mentioned conventions and treaties and states the intention to regulate the processing of personal data consistent with these fundamental rights (Directive 95/46/EC 1995, preamble, p. 10). The Data Protection Directive defines *personal data* as information relating to an identified or identifiable natural person (Directive 95/46/EC 1995, article 2a). Examples of personal data related to e-mail and Internet communications include the sender's and receiver's names, as well as their e-mail or Internet addresses, postal addresses, phone numbers, etc. Although privacy as a fundamental right is also recognized in international law, there is no specific recognition in international law of data protection as a fundamental right similar to that found in the European Union (International Covenant on Civil and Political Rights 1966, article 17).

There is no universally recognized standard for protecting personal data as a fundamental human right. However, the EU approach provides a system that comprehensively regulates the processing of personal data consistent with fair information practices (EU Charter 2000, article 8(2)). Fair information practices include: (1) defining the obligations of those using personal data and limiting the use of personal data; (2) mandating transparent data-processing systems; (3) providing at least minimum procedural and substantive rights for data subjects; and (4) providing external oversight of data-processing activities by a governmental or other independent body (Schwartz 1999).

The EU Model of Workplace Privacy Rights

In the European Union, employees have privacy and data protection rights according to the national laws of the country in which they live, including workplace-specific laws and personal data protection legislation implementing the EU's Data Protection Directive (Delbar, Mormont, and Schots 2003; Lasprogata, King, and Pillay 2004). Workplace-specific laws in EU member countries that protect the privacy of employees' e-mail and Internet communications are found in:

- labor statutes
- labor agreements (which may be national in scope)
- criminal statutes that protect the secrecy of private e-mail messages (as opposed to business enterprise-related messages) and may require consent for monitoring
- civil statutes that apply when an employer has permitted private e-mail and Internet use by employees
- court decisions (including those requiring employers to have issued clear policies or instructions on e-mail and Internet use before disciplining employees for misuse)

In some countries, works councils and other employee representatives may have legal rights to agree to or to be informed and consulted about workplace privacy policies

and procedures, including the right to be consulted before new technology such as e-mail or Internet monitoring equipment is introduced in a workplace.

Each country in the European Union is also required to adopt legislation to implement the EU Data Protection Directive. This Directive protects the privacy of individuals (referred to as "data subjects") when their personal data are processed. The EU Data Protection Directive regulates the quality of personal data, requiring that it be processed fairly and lawfully, be collected for legitimate purposes, be relevant, be accurate, and be kept in a form that permits identification of data subjects for no longer than is necessary for the purposes of the collection (George, Lynch, and Marsnik 2001). The EU Data Protection Directive also sets criteria for legitimate processing of personal data. To process personal data of employees or customers, in some cases employers are required to obtain consent from the data subject. In other cases, consent is not required, but the employer may process personal data only when it is necessary for performance of a contract with the data subject, necessary for the controller of the personal data to meet its legal obligations, or allowed for other specified reasons. There are special rules that severely limit the processing of special categories of personal data that would reveal race, ethnic origin, political opinions, religious or philosophical beliefs, trade union membership, health, or sex life. The EU Data Protection Directive requires collectors of personal data to inform the data subject about the processing of data and to give the person access to data about themselves. The party responsible for processing personal data must make sure the processing is confidential and secure and notify a designated government monitoring authority prior to processing.

In the EU there are restrictions on the transfer of personal data outside the EU that impact e-mail and Internet use policies. For example, General Motors Company ("GMC") found that its plan to update its electronic company phone book to include office phone numbers for employees around the world was covered by the EU Data Protection Directive because it involved sending the employees' office phone numbers outside the EU (Scheer 2003). To comply with the EU Data Protection Directive, GMC was required to get the approval of the government privacy agency in the European countries where its employees worked and to satisfy rigorous personal data transfer rules before issuing the global phone book. Among other obligations under the EU Data Protection Directive, GMC was required to make disclosures to employees whose personal data would be included in the phone book and to consult with employees' labor representatives where appropriate. There is no reason to believe that employees' e-mail addresses would be treated differently than their office phone numbers, so the EU Directive would apply to global e-mail directories as well.

Since the EU has determined that the laws of the United States do not provide an adequate level of privacy protection consistent with the Data Protection Directive, transfer of personal data about customers or employees from the European Union to the United States is severely restricted. Generally, to make such a transfer, the recipient in the United States must make a commitment to follow the Safe

Harbor Agreement of the U.S. Department of Commerce (U.S. Department of Commerce 2000). Alternatively, the transfer of data from the European Union must be subject to a contract that includes EU-approved model contractual clauses designed to provide an adequate level of privacy protection for the personal data of EU residents.

Despite the existence of comprehensive privacy and data protection rules in the European Union, there is little employment-specific legislation related to policies and practices covering workplace privacy and e-mail or Internet use. For more specific guidance, employers drafting workplace e-mail or Internet use policies may also consult guidance and opinions issued by government bodies in the European Union on privacy in the workplace and employees' e-mail and Internet use (Lasprogata, King, and Pillay 2004). For example, the Information Commissioner in the United Kingdom published *The Employment Practices Data Protection Code* to provide guidance to employers on the process of complying with the United Kingdom's personal data protection act and offers good practice recommendations for employers (United Kingdom Information Commissioner 2006).

The U.S. Perspective on Workplace Privacy

Unlike the European approach, the U.S. has no comprehensive privacy or data protection regulation that applies to workplace privacy. When drafting an e-mail or Internet use policy for employees in the United States, employers need to be aware of myriad laws, including common law privacy tort law, laws related to employment relationships, and federal and state privacy legislation. However, taking all these laws into account, U.S. employees have significantly fewer workplace privacy and data protection rights than their European counterparts.

U.S. tort law gives employees working in the private sector only limited privacy rights. The privacy tort that is most frequently applied to workplace privacy issues is the tort of intrusion into seclusion, which covers employers' intrusions into employees' private affairs (Rothstein 2000). If an employer intentionally intrudes, physically or otherwise, upon the solitude or seclusion of the employee in her private affairs or concerns, and a reasonable person would find the intrusion highly offensive, the employee may be able to recover damages for invasion of privacy under tort law (Rothstein 2000). However, courts have generally found that private-sector employees in the United States have no reasonable expectation of privacy that prevents their employers from engaging in intrusive behavior in the workplace, such as monitoring and other surveillance. The rationale of courts is that employees give up workplace privacy rights by agreeing to work for their employers. Also, sound business reasons often are found to justify actions by employers that are viewed by employees as invasions of privacy, such as the need to investigate complaints that employees have used employers' e-mail systems to harass other employees. When an employer has a company policy that prohibits misuse of its e-mail or Internet system, the policy may serve to reduce expectations of privacy by employees in their use of e-mail

or Internet systems, thus helping the employer defend privacy tort cases. For example, in *Garrity v. John Hancock Mutual Life Insurance Company* (2002) the court dismissed employees' claims of invasion of privacy based on their employer's reading of their e-mail on the employer's computer system. The court held that the employer's policy prohibited employees from using the employer's e-mail system to send or receive sexually explicit material and the employees had violated the employer's policy by sending and receiving sexually explicit e-mail messages; thus the employees had no reasonable expectation of privacy in their office e-mail.

The laws governing employment relationships also provide U.S. employees with few workplace privacy rights related to e-mail and Internet use policies. The basic rule is that unless private-sector employees have statutory or contractual rights to privacy, they have no privacy rights that limit their employer's ability to impose e-mail or Internet use policies or to engage in electronic monitoring of e-mail and Internet use in the workplace (Cottone 2002). In contrast, employees covered by collective bargaining agreements may have contractual rights to privacy that arise from those agreements. Collective-bargaining agreements may also restrict employers' rights to terminate employees without just cause, notice, and procedural process (Cottone 2002; National Labor Relations Act of 1935). Also in contrast to private-sector employees, public employees may have rights to privacy and protections from arbitrary termination that are based on civil service legislation and state or federal constitutions (Cottone 2002; *U.S. v. Simmons* 2000).

Unlike employees in most other countries, employees in the United States are often employed "at will." Under employment at will, employers may discipline or discharge an employee for almost any reason or for no reason, as long as the discharge is not contrary to law (including law established by statutes, court decision, and/or contracts) (Cottone 2002). Many exceptions to at-will employment have been developed in statutes or by the courts, and these exceptions limit an employer's prerogatives to discipline employees and terminate their employment. For example, it is unlawful under federal discrimination statutes for an employer to treat employees differently with respect to terms and conditions of employment based on their sex, race, color, national origin, religion, age, or disability (Title VII of the Civil Rights Act of 1964; Age Discrimination in Employment Act of 1967; Americans with Disabilities Act of 1990). At-will employees are also protected from wrongful discharge for reasons that violate public policy, such as exercising a legal right to file a workers' compensation claim, to serve jury duty, or to come to the aid of a person known to be in serious danger (*Frampton v. Central Indiana Gas Co.* 1973; *Garner v. Loomis Armored, Inc.* 1996). Another exception to at-will employment protects employees covered by individual employment contracts that provide contractual rights greater than at-will employment, such as a right to be discharged only for just cause (Cottone 2002; Leonard 1988).

Typically, at-will employees have no privacy or other employment rights that limit their employers' ability to impose and enforce e-mail or Internet use policies or engage in electronic monitoring of the workplace (Cottone 2002).

In contrast, in unionized workplaces in the United States, where employers generally have an obligation to bargain over terms and conditions of employment, employers may not be able to unilaterally impose e-mail or Internet use policies, at least if unionized employees may be disciplined for violations of the policy. In addition, once collective bargaining agreements are in place, unionized employees may have contractual rights to privacy that arise from the collective bargaining agreements, and their collective bargaining agreements may also restrict employers' rights to terminate employees without just cause, notice, and procedural process, including arbitration to resolve any disputes (Cottone 2002; National Labor Relations Act of 1935). Also, in contrast to at-will employees, public employees (those working for government employers) may have rights to privacy and protections from arbitrary termination that are based on civil service legislation and state or federal constitutions (Cottone 2002; *U.S. v. Simmons* 2000).

When drafting e-mail and Internet use policies, at-will employers often document the at-will employment relationships they have with employees in policy language and will include disclaimers designed to limit the likelihood that courts will interpret the policies to create contractual obligations other than at-will employment. Sometimes, at-will language and disclaimers will be included in the body of e-mail and Internet use policies. In other cases, when employers' e-mail and Internet use policies are included in employee handbooks containing other policies, at-will language and disclaimers will often be found in the introductory sections of the handbooks to avoid repetition in individual policies. At-will language typically states that employment at a company is at will and clarifies that either employers or employees may terminate the employment relationship at any time, without advance notice, and for any reason except one prohibited by law. Disclaimer statements for at-will employees generally state that policies and/or handbooks are only a guideline for employees and supervisors and do not create contractual relationships that differ from at-will employment.

Whether employees in the United States are at will, covered by a collective-bargaining agreement or other employment contract, or working for public employers, federal and state privacy statutes may impose privacy requirements on employers that are related to drafting e-mail and Internet use policies. However, federal statutes designed to protect the privacy of electronic communications provide only limited privacy protection for employees in the context of e-mail and Internet communications in the workplace (Lasprogata, King, and Pillay 2004). The Electronic Communications Privacy Act of 1986 (ECPA) is the primary federal law that protects the privacy of electronic communications, including the contents of e-mail and Internet chat. The ECPA prohibits wiretapping and unauthorized access to communications in electronic storage (*Konop v. Hawaiian Airlines* 2002). Under these federal privacy statutes, it is unlawful for anyone, including an employer, to intentionally "intercept" the content of a wire, oral, or electronic communication (Title I violations) (ECPA 1986). It is also a federal crime for anyone to "access" a facility providing electronic communication service without "authorization" and thereby obtain access to a wire or

electronic communication while it is in electronic storage (Title II violations) (ECPA 1986).

Unless the interception or unauthorized access of a wire, oral, or electronic communication is covered by one of several statutory exemptions or authorized or required by law or a government order, violation of these statutes is a federal crime. Fortunately for employers, there are many exceptions to the ECPA that permit employers to adopt e-mail and Internet use policies and reserve the right to monitor the use of their equipment and systems. For example, Title I contains exceptions for "business use in the ordinary course of business," "providers of communication systems," and "consent" (Kesan 2002; Sidbury 2001). Title II contains exceptions for "providers of communications" and "authorization by users of communications systems" (Kesan 2002; Sidbury 2001). Employers who want to reserve the right to monitor their employees' use of e-mail and Internet access systems need to consider the ECPA and its exemptions when drafting their policies.

Although the ECPA restricts access only to the contents of electronic communications, the distinction between the contents of an e-mail and other information related to the e-mail communication may not be obvious. The ECPA does not restrict the employer's access to information about e-mail or Internet communications that is analogous to the addressing information on the outside of a letter sent through the U.S. mail. But is the subject line of an e-mail content or addressing information? A Federal Circuit Court of Appeals recently held that interception of Internet search queries was covered by the ECPA (*In re Pharmatrak, Inc. Privacy Litigation* 2002). For example, an Internet search query containing the key word "breast cancer" may reveal a lot about the subject of an employee's Internet search, particularly if it is captured along with personally identifying information about the sender of the query, like the sender's name. Fortunately for Pharmatrak, the case was remanded to the district court to determine whether Pharmatrak intended to intercept the contents of electronic communications, a necessary element of an ECPA violation. The court found there was no evidence that Pharmatrak intentionally intercepted the electronic communications, and dismissed the case. Based on the *In re Pharmatrak, Inc. Privacy Litigation*, employers would be wise to view personal information contained in Internet queries as contents of employees' communications, rather than mere addressing information that would not be covered by the ECPA.

In addition, employers who adopt e-mail and Internet use policies and communicate those policies to employees may qualify for the ECPA's exemptions covering interception or access to electronic communications with employees' consent. Additional tips for compliance with the ECPA exemptions are found later in this chapter in the section on "Reserving the Employer's Right to Conduct Electronic Monitoring." Finally, the exemption for interceptions of electronic communications in the ordinary course of business also permits some employer monitoring of e-mail and Internet access. However, in the context of telephone communications, courts have held that this exemption does not permit the employer to listen to personal conversations, and the employer must stop listening when a communication is found to be personal

(*Fischer v. Mt. Olive Lutheran Church* 2002). In *Fischer*, the court held that once the employer became aware that an employee, a youth counselor, was having a sexually explicit conversation with another adult and not a minor, the employer should have known the employee's conversation was not job-related. At that point, listening in on the employee's conversation was no longer covered by the ECPA's exemption for interceptions in the ordinary course of business and was therefore a violation of the ECPA.

The ECPA sets a minimum privacy protection for electronic communications, including those of employees. However, state wire-tapping statutes may be more protective of electronic communications privacy rights (United States Government Accounting Office 2002) and should also be reviewed when drafting a policy. For example, Florida's Security of Communications Act is stricter than the ECPA and prohibits intercepting or disclosing the contents of any electronic communication without obtaining the consent of both the sender and the recipient. The Florida statute covers interceptions and disclosures of workplace communications even when the employer provides the e-mail system (Florida Statute 2005 §934.01 *et seq.*; Safon 2000). In addition, some states have statutes that specifically restrict the employer's ability to monitor e-mail without employee consent (Burgunder 2004; Safon 2000). These workplace-specific laws are discussed next.

In addition to state tort laws related to privacy and state wiretapping statutes similar to the ECPA, some states have specific statutes that affect employment policies such as e-mail and Internet policies. For example, Connecticut has a statute that prohibits employers from electronically monitoring employees' e-mail without giving employees prior written notice, except in certain circumstances. One of the exceptions allows employers to electronically monitor employees' e-mail when there are reasonable grounds to believe an employee has violated the law or engaged in conduct that creates a hostile work environment (Connecticut General Statutes 2005). Other states have statutes that prohibit monitoring e-mail without employee consent (Burgunder 2004; Safon 2000, 101, 102). Finally, some states have statutes that prohibit employers from using employees' lawful, off-duty conduct as a reason for termination (see, e.g., Cardi 2004). It is not a far stretch to imagine a court interpreting state laws that protect employees' lawful, off-duty conduct from invalidating discipline or discharge of employees for violating an employer's e-mail and Internet use policy when that policy seeks to regulate the employees' off-duty use of e-mail and Internet access. Under these statutes, employees discharged for off-duty conduct that violates employers' e-mail and Internet use policies may have a remedy for wrongful termination.

Designing Global Policies for Multinational Employers

Multinational employers face special challenges when designing e-mail and Internet use policies. Outside the United States, employment at will is less likely to be a legally recognized employment relationship—even if employment at will is lawful, employees often have heightened privacy and data protection rights under national

laws and regional agreements. One of the challenges for private businesses that are multinational employers is designing e-mail and Internet use policies that are consistent with employees' privacy and data protection rights in countries other than the United States. The European Union is recognized as the leader in providing the greatest level of privacy and data protection for employees in the workplace (George, Lynch, and Marsnik 2001). Because the European Union has the most rigorous privacy and personal data protection laws, multinational employers may choose to comply with EU rules when drafting e-mail and Internet use policies in order to have uniform global policies. For an example of a global privacy policy adopted by a multinational company with operations in the EU, see Hewlett-Packard's global master privacy policy (Hewlett-Packard 2006) (this global privacy policy is not specific to the context of e-mail and Internet use). Because of the increasingly global nature of business today, employers in the United States may eventually be subject to regulations that require providing privacy and personal data protections for workplace communications consistent with the principles found in EU law. In addition, adopting a global e-mail and Internet use policy consistent with EU privacy protections may make sense for many multinational companies because other countries are adopting privacy laws consistent with those of the European Union, including Canada, Australia, New Zealand, South America, and parts of Asia (Scheer 2003).

SCOPE OF E-MAIL AND INTERNET USE POLICIES

An important strategic decision that an employer must make when drafting an e-mail and Internet use policy is the scope of the policy. An initial scope issue is the breadth of technologies to cover, including wireless access, cell phones, instant messaging, blogs and other communications avenues, and tools currently available or under development (2005 AMA Survey). The scope of the policy will also be expanded or limited by the employer's decisions regarding whether to permit personal use of its e-mail and Internet systems, whether to limit application of the policy to employer-provided equipment and systems, and whether to cover off-premises use of its e-mail and Internet systems.

Evolving Forms of Electronic Communications

An employer's policy should be drafted to cover the multitude of communications devices and technologies that can be used by employees to send and receive e-mail and access the Internet (Honda and Martin 2002). Currently, this means the employer's policy should cover the use of cell phones and personal digital assistants (PDAs) supported by wireless technology and the use of instant messaging capability (2005 AMA Survey). To avoid having its policy become technologically outdated, the employer's policy should be worded to encompass new technologies as they become available even if wireless or other e-mail

and Internet access capabilities are not currently provided by the employer for its employees' use. This is because wireless technology permits employees to access e-mail and the Internet from the workplace with or without using the employer's e-mail or Internet access equipment or systems. For example, employees with a personal cell phone or personal PDA with Internet capability can send or receive e-mail or access the Internet to chat and send text or instant messages while in the workplace and without using the employer's systems or equipment (Honda and Martin 2002). Employees may have their own communications equipment in the workplace, enabling them to download pornography or copyrighted music in the workplace or to send messages containing the employer's trade secrets from within the workplace to an outsider.

Cell phone use in the United States is ubiquitous and is growing globally. One survey showed that 59 percent of people in the United States use cell phones, more at work than at any other location (Smith 2005). In Europe, where the device is more likely to be called a mobile phone, the rate of cell phone use is even higher. Approximately 88 percent of Europeans use mobile phones (European Mobile Statistics 2004). The use of cell phones on the job for work or personal reasons can be expected to grow.

Although it is estimated that less than one in five U.S. employees use instant messaging, internationally the practice may be more widespread. For example, it is estimated that about 65 percent of employees in the United Kingdom use instant messaging (that may be communicated with or without using wireless devices). Potential uses of instant messaging with workplace ramifications include "flirting with colleagues, scheming against the boss and gossiping about coworkers," or even sending "sensitive information about major corporate projects" to competitors (Reuters 2003). Many employees who use instant messaging wrongly assume that instant messages cannot be monitored by the boss (Reuters 2003). Also troubling for employers is the risk that employees will use instant messaging in unprofessional or even discriminatory ways, such as logging on as "cutelilpixiechick" or sending sexual jokes through instant messaging (McClure 2003, 31). Thus, the use of wireless technology and/or instant messaging should be covered by an employer's e-mail and Internet use policy and raises valid productivity and legal risk considerations for employers.

At a minimum, the employer's e-mail and Internet use policy should cover the use of wireless technology by employees while they are at work, whether the wireless technology is provided by the employer or the employee. In the policy, the employer should also address scope issues in the context of wireless devices, including whether to: permit reasonable personal e-mail and Internet access on the job using wireless devices; apply the policy to e-mail and Internet access using wireless devices if employees are not on the employer's premises; or cover wireless access that also involves use of the employer's systems and equipment. In the policy, the employer also should anticipate that new ways of communicating electronically will be used by employees, such as text messaging, instant messaging capability, or Voice over the Internet Protocol (VoIP). See the next section for a discussion of some important legal constraints on imposing a policy with a broad scope.

Business Use versus Personal Use

An important question for employers to answer is whether to limit employees' use of the employer's e-mail and Internet systems to "business use only," thus excluding any personal use of these systems provided by the employer. Generally, employees have no legal "right" to use the employer's e-mail and Internet systems for personal reasons, so an employer may lawfully adopt a business-use-only policy (King 2003, Labor law for managers). However, in view of the fact that many people work long hours, some advocates for privacy in the workplace argue that it has become accepted that there will be a certain amount of personal business that will be done during business hours, including personal e-mail communications (Sidbury 2001). Realistically, some employees will use e-mail and Internet communications for some personal use regardless of the prohibitions found in any employment policy (Anandarajan and Simmers 2004).

An advantage of permitting some personal use is that employees may be better able to balance work and family conflicts by having access to e-mail and Internet systems for some personal uses, such as family emergencies, monitoring the after-school activities of children, checking in with a spouse, and so forth. Personal use of e-mail and Internet access for these types of reasons may be less disruptive in the workplace than employees' use of telephones and/or cell phones, because the communications are generally "silent" and less likely to disrupt the work of other employees. Furthermore, allowing reasonable personal use of e-mail and Internet access may result in less loss of work time by reducing absenteeism at little or no additional cost to the employer. Allowing reasonable personal use of the employer's e-mail and Internet access may generate positive employee morale and may also encourage employees to keep abreast of technological developments. Current research supports the conclusion that there are some positive beneficial side effects of permitting employees to surf the Web at work (Anandarajan and Simmers 2003).

On the other hand, limiting e-mail and Internet access to business-use-only policies may discourage employees' abuse of work time for personal reasons, reduce the need for management to supervise employees' use of e-mail and the Internet to prevent excessive personal use, and limit the likelihood that employees opening personal e-mail on their employer's systems will infect the employer's system with computer viruses.

Blurring of Workplace Boundaries: Virtual Workplaces

One of the advantages of e-mail and Internet technology is that it permits work to be done by employees from just about anywhere. For employees who conduct business using the Internet and Web sites or using a cell phone or other mobile wireless technology, the workplace is primarily a virtual workplace as opposed to a physical one. The blurring of workplace boundaries and emergence of virtual workplaces challenge policy drafters to clearly define the scope of policies. A question for policy drafters to consider is whether there are special concerns when an

employee works in a virtual workplace. For example, do virtual workers have stronger arguments in favor of reasonable personal use of employer-provided Internet access or e-mail via cell phones because the virtual workplace is their primary workplace? Of course, employees may carry personal cell phones or PDAs to use for personal communications, so perhaps business-use-only policies related to employer-provided equipment will be justified even in virtual workplace scenarios because such policies do not foreclose use of personal communications devices. Even when employers adopt business-use-only policies, the use of personal cell phones by employees in the workplace and the impact on work time and productivity are issues to be addressed in the employers' policies.

Even for employees in traditional workplaces, communications technology has blurred workplace boundaries. Should the employer's e-mail and Internet use policy also cover e-mail and Internet access by employees on their home computer systems and conducted on their own time? If on the employees' own time, and from their homes, employees use their laptops and their own Internet service providers (ISPs) to send e-mail messages to their coworkers' personal e-mail accounts, should the employers' policy apply? If one assumes that the employees' e-mail messages may expose the employers' trade secrets in an insecure environment, it seems clear that employers have valid business interests in applying their policies. What if employees use their own laptops and ISPs to chat online and in so doing make derogatory statements about their bosses that members of the public may access, potentially harming the employers' reputations with their customers? In both of these situations, the employees are not using the employers' systems or equipment or making the communication on work time, but the online conversations arguably relate to their workplaces and involve legitimate employers' interests. From a management perspective, considering the potential harm to the employers' businesses, these types of communications probably should be covered by the employers' policies. However, caution should be exercised when drafting policies that regulate employees' use of e-mail or the Internet outside the workplace. In Europe and other countries that protect individual privacy as a fundamental human right, employers who regulate employees' personal communications will be viewed as interfering with individual rights, such as the individual right everyone has "to respect for his private and family life, his home and his correspondence" (ECHR, Article 8, 1950; ICCPR, Article 17, 1966). In 2007, the European Court of Human Rights ruled that a public-sector employee was entitled to damages and court costs from her employer, the U.K. government, for monitoring that violated Article 8 of the Convention on Human Rights. In that case, a college monitored the employee's personal Internet usage and telephone calls without informing her in advance that her communications might be monitored (*Copland v. United Kingdom* 2007; Espiner 2007).

Non-union, private-sector employees in the United States do not generally have legally recognized fundamental rights of privacy in their personal communications. However, in some states, private-sector employees have constitutional free speech rights or rights to engage in

lawful off-duty conduct that protect them from intrusive private-sector employers (Safon 2000). In addition, public-sector employees have free speech rights with respect to their governmental employment under the U.S. Constitution (*O'Connor v. Ortega* 1987).

Many e-mail and Internet use issues also involve employees using their own computer systems and ISPs to access the employer's computer systems. This was the case in *Smyth v. Pillsbury Co.* (1996), in which an employee sent an e-mail from his home to another employee by accessing the company's e-mail system. In his e-mail message, the employee made derogatory references about another manager that included a threat to "kill the backstabbing bastard" and compared an upcoming holiday party to a "Jim Jones Kool-Aid Affair." The employer obtained copies of the employee's e-mail and, not surprisingly, terminated his employment for inappropriate use of the company's e-mail system. The court in *Smyth v. Pillsbury* held that the employee lost any reasonable expectation of privacy by sending his e-mail over the employer's e-mail system, and denied the employee's claim that his discharge was in violation of public policy.

Outside the United States, the outcome of a similar case would not be so predictable if brought by employees who have legally recognized personal privacy rights even when they use their employer's e-mail systems for personal communications. For example, in *Halford v. United Kingdom* (1997), the European Court of Human Rights (ECHR) rejected an employer's argument that the employee had no reasonable expectation of privacy when she made personal telephone calls from business premises using a company phone. The court held that the employee's calls were covered by notions of "private life" and "correspondence" that are fundamental individual privacy rights in Europe, particularly since the employee had no warning that her calls could be intercepted.

In *Smyth v. Pillsbury*, both employer- and employee-provided equipment and systems were being used and the communication was both personal and work-related. Such situations involving blurred workplace boundaries are likely to be increasingly frequent as e-mail and Internet access become increasingly pervasive in our society. To help prevent misuse of e-mail and Internet systems that may harm employers' legitimate business interests, employers' policies may, and probably should, cover any use of employer-provided computer equipment, e-mail, or Internet access, even if employee-provided equipment and/or systems are also used, and even if the communications are "personal." The employer's interest in including these types of communications within its e-mail and Internet use policy is stronger if the employer has provided at least some of the e-mail and Internet equipment or systems. In addition, contemporary workplace violence and harassment concerns merit a broadly worded policy. However, drafting a policy to address improper use of e-mail and the Internet is difficult. Drafters need to consider how to define misconduct under the policy, the consequences for policy violations, and whether the policy will enable an employer to engage in electronic monitoring to investigate noncompliance. As this chapter explores, employers' prerogatives to set workplace rules for e-mail and Internet use and to investigate and discipline employees for

improper use often depends on the laws of the countries where employees work. Employers will have relatively more latitude to do these things in the United States and in other countries where employees do not have extensive privacy and other legal rights in the workplace. On the other hand, employers will have less latitude in drafting workplace e-mail and Internet use policies in Europe and other countries where employees have extensive privacy and other legal protections related to their e-mail and Internet communications.

Employee Blogging

One of the most recent challenges to managing a workforce is employee "blogging" (Gutman 2003). "A blog, short for web log, is a journal or diary posted on the Internet" (Cobey and Gordon 2005). It is estimated that 10 million Americans maintain their own blog, which can serve many purposes, such as political commentary, recruitment, venting, or commenting on a person's work life and coworkers (Cobey and Gordon 2005). Although some employers have discouraged blogging by their employees, others have embraced blogging as a means of promoting employee creativity and constructive dialog about the workplace (Cobey and Gordon 2005). Blogging by an employee may create broad employment liability concerns for employers, including employer liability for employees' blogging that is criminal, defamatory, or violates copyright laws (Gutman 2003, 150). Employees' blogging may disclose confidential business information or undermine a company's public image (Cobey and Gordon 2005). Some employers have been fired because they have posted harmful content on their blogs, including a flight attendant who described herself as "Queen of the Sky" and posted pictures of herself in her uniform showing more skin than usual, and a U.S. Senate staff member whose blog contained thinly disguised descriptions of the sexual escapades of her coworkers (Cobey and Gordon 2005). To prevent employees from blogging in ways that harm company interests and create company liability, employers should address these concerns in their Internet use policies. Employers should also prohibit blogging that would violate the law. For example, employees' disclosure of confidential information about the company on a blog could cause a drop in a publicly traded company's stock price, potentially violating U.S. securities laws.

Recent litigation by Apple Computer illustrates the risk that employees may use blogs to improperly disclose companies' trade secrets. Apple subpoenaed records related to a lawsuit claiming unknown persons (DOEs) had violated Apple Computer's trade secrets by communicating the trade secrets to online publishers who then published the trade secrets (*Apple Computer v. DOE 1-25 2005*). Apple Computer's subpoena sought evidence that could reveal the identities of the people who supplied the company's trade secrets to the online publishers. The trade secrets included details of a new product to be produced by Apple that had not yet been publicly announced. The trial court considered a motion by the online publishers to dismiss the subpoena. Although the trial court initially ruled in favor of Apple, ordering the enforcement of the subpoena, the California Court of Appeal reversed, ordering the trial

court to grant a protective order to prevent Apple from issuing subpoenas to identify the sources of stories (*O'Grady v. Superior Court (Apple Computer, Inc., Real Party in Interest)* 2006; Hiltzik 2005). The appellate decision is consistent with protecting the free speech rights of the online publishers not to reveal news sources (Hiltzik 2005), but impacts the ability of companies to discover the identities of employees and former employees who anonymously post online messages that disclose confidential company information in violation of company policies.

The determination of whether the scope of the employer's policy should include e-mail and Internet access involving employee-provided equipment, communications made outside the employee's work time, and personal as opposed to work-related communications involves weighing management as well as legal concerns. For more discussion of U.S. legal constraints on the scope of e-mail and Internet use policies, see "Additional Tips on Complying with U.S. Employment Laws in Table 1."

COORDINATING E-MAIL AND INTERNET USE POLICIES WITH OTHER POLICIES

E-mail and Internet use policies typically involve issues that are related to other business practices and policies. The most obvious connection is between e-mail and Internet use policies and the company's privacy practices and policies. Because of the number of privacy issues related to e-mail and Internet use policies, a company should consider drafting a company privacy policy that covers employee privacy. With a general privacy policy in place, a company may refer to it in its e-mail and Internet use policy.

Another area of coordination between company practices and policies involves the retention of stored e-mail and Internet access records and a company's document-retention policies. There are obvious risks related to retaining e-mail and Internet use records indefinitely, including the risk that the company will be required to sort and produce e-mail and Internet use records in litigation that may be filed in the future against the company. On the other hand, the company needs to be able to retain and produce e-mail and Internet use records related to discovery requests in pending or threatened litigation. For these reasons, a company's e-mail and Internet use policy should be consistent with its document-retention policies for electronic documents and records.

A company's e-mail and Internet use policy also involves issues of confidentiality of employees' records, including policies for granting access to e-mail communications and Internet access information. Employees are often concerned about the privacy of their e-mail communications and favor limiting their employer's access to records about their e-mail and Internet use. The employer often favors broad employer access to employees' electronic communications and records of Internet access for valid business reasons. Valid business reasons to reserve employer access to employees' electronic communications and Internet access records include investigating complaints of misconduct, responding to discovery requests related to litigation,

and monitoring misuse of e-mail and Internet systems. If the company has a separate policy regarding confidentiality of employee records, it should be consistent with the company's e-mail and Internet use policy.

A serious concern of businesses today is violence in the workplace and national security threats. Many companies have separate policies prohibiting violence in the workplace and requiring employees to report threats of violence in the workplace and other threats. It is important to consider that threats of violence may be communicated by e-mail or Internet chat, and the employer and/or law enforcement may need access to e-mail and Internet systems to respond to threats of violence. On a broader scale, national security threats may also involve the use of e-mail and Internet systems. Coordination of e-mail and Internet use policies with workplace violence policies and national security interests is crucial to enable appropriate responses to threats of violence and other security issues.

COMMUNICATING E-MAIL AND INTERNET USE POLICIES TO EMPLOYEES

A critical component of being able to enforce an e-mail and Internet use policy is communicating the policy to employees and others covered by the policy, such as independent contractors. There are various ways to communicate an e-mail and Internet use policy to the people who will be covered by the policy. A traditional way to communicate a workplace policy is to distribute a paper copy of the policy and to require written acknowledgment from the user that he or she has read and understands the policy. The user's acknowledgment generally becomes part of company records. Some employers electronically distribute their e-mail and Internet use policy to users of their e-mail and Internet use systems on a regular basis. To proceed and use the e-mail or Internet system, users of the system may periodically be required to scroll through the policy and to "click" on a statement indicating that the user has read and understands the employer's e-mail and Internet use policy. Electronic records of the user's acknowledgment of receipt of the policy may then be kept.

Another method of communicating an employer's e-mail and Internet use policy is to provide training for users of the system. The training may be part of new employee orientation. Training may also be provided for existing employees and other systems users on a periodic basis. The possibility of providing online training about using the employer's e-mail and Internet systems should also be considered. Certainly managers and supervisors responsible for implementing the e-mail and Internet use policy should receive training on administering the policy. A key component of training for managers and supervisors is to communicate the employer's philosophy about respecting employees' privacy consistent with protection of the employer's legitimate interests.

A critical issue regarding communication of the employer's e-mail and Internet use policy is to make sure it is communicated to all covered users of the employer's systems, including the employees of independent contractors that use the company's e-mail and Internet systems. Compliance with the employer's e-mail and Internet use

policy should be referenced in any written agreements with independent contractors, staffing services, or other users of the employer's systems.

ENFORCING THE POLICY

A key point related to designing and implementing effective e-mail and Internet use policies is that even the best-designed policy will fail if it is not enforced consistently and fairly. A policy that is not followed consistently by the employer may lead to discrimination complaints when an attempt is made to enforce the policy. Such discrimination complaints may protest inconsistent enforcement of a policy against members of any legally protected class, including classes of persons based on race, sex, national origin, disability, or age. In addition, even in nonunion workplaces, employees may file unfair labor practices complaints when an employer enforces an e-mail or Internet use policy in a way that discriminates against employees who are engaging in collective action related to their terms and conditions of employment. For example, selective discipline of an e-mail "griper" who sends an e-mail to coworkers complaining about the employer's new vacation policy may turn into an unfair labor practice complaint. If the employer's e-mail and Internet use policy prohibits all nonbusiness use of its e-mail and Internet systems, this type of e-mail message would violate the policy. However, if the employer disciplines the "griper" for sending personal e-mails but has not disciplined other employees for making personal use of its systems, it has inconsistently enforced the policy. In these types of situations, a court or administrative agency may reverse the discipline and order damages, effectively preventing the employer from enforcing its policy. See the discussion of discrimination and harassment concerns and federal labor law issues found in the section on "Additional Tips on Complying with U.S. Employment Laws."

PROTECTING THE EMPLOYER'S TRADE SECRETS AND OTHER PROPRIETARY INFORMATION

An e-mail and Internet use policy is an important tool to protect a company's trade secrets, such as marketing strategies, customer lists, price lists, expansion plans, and other company documents containing confidential and proprietary information that a company would like to keep secret from its competitors. When a company's trade secrets have been made publicly available, the information may lose its protection under trade secret law because it is no longer secret. This is because an essential component of the law's protection for a company's proprietary information is that the information is in fact not public knowledge. The employer's e-mail and Internet use policy should also prohibit employees from pirating trade secrets from former employers or competitors, thus exposing the current employer to litigation for trade secret infringement lawsuits under state trade secret laws. Trade secret theft is also a federal crime under the Economic Espionage Act of 1996, which provides for fines up to 5 million dollars against corporations as well as imprisonment and hefty fines for individuals.

Agreements Covering Employees

An e-mail and Internet use policy is often supplemented by other preventive steps that may reduce the risk of loss of the company's trade secrets and the risk of liability for infringing on the trade secrets of other companies. For example, an employer may develop written noncompetition and/or nondisclosure (confidentiality) agreements for employees to sign (Garrison and Stevens 2003). An employer may also require job applicants or new employees to sign statements that they are not bound by noncompetition or confidentiality agreements related to former employers and to agree that they will not use information that belongs to others, including information protected by trade secret laws. In the United States, because employees owe fiduciary duties of loyalty to their employers under state agency laws even when they have not signed a formal written agreement, a written agreement may not be required for employers to address breaches of confidentiality by employees. A contemporary issue involves the inevitable disclosure doctrine, which provides a remedy for employers similar to an unwritten noncompetition agreement in circumstances in which employees leaving the workplace to work for a new employer cannot avoid sharing or relying on trade secrets from their former employer (Frauenheim 2005). In states that accept the inevitable disclosure doctrine, employers can sue former employees using this doctrine even if they have signed only a nondisclosure agreement or if they have not signed any agreement (Frauenheim 2005).

Agreements Covering Nonemployees

Employers using the services of independent contractors or their employees should also consider requiring noncompetition agreements or nondisclosure agreements to protect company trade secrets. When nonemployees are given access to company e-mail or Internet access, the employer has valid concerns that can be protected by requiring nonemployees to sign these types of agreements. If the employer's e-mail and Internet use policy covers nonemployees, the employer should make sure to clarify that requiring nonemployees to comply with the policy does not create any employment rights or change the nonemployees' status as independent contractors.

Noncompetition agreements and nondisclosure agreements also have an important role to play in protecting the privacy and personal data stored in the employers' databases. For a discussion of the legal risks and obligations to protect the privacy and personal data of customers, employees and others, see the sections on "Protecting the Employer's Computer Networks" and "Protecting the Personal Data of Third Parties."

PROTECTING THE EMPLOYER'S COMPUTER NETWORKS

E-mail and Internet use policies have an important role to play in protecting the employer's computer networks from threats such as spam, spyware, and unauthorized access by outsiders. Employees' use of e-mail and Internet access may expose the employer's computer networks to these threats. Thus, the employer's policy is a tool to

educate employees about the threats and what they can do to help prevent damage to the employer's computer networks.

SPAM

Spam, unsolicited e-mail communications, is analogous to junk mail sent through regular mail. Spam may be sent for commercial purposes, including advertising goods and services, or to solicit donations for nonprofit organizations or political campaigns. Because spam is often sent through mass e-mailings to a large number of recipients, it may overburden companies' e-mail systems. Spam e-mail may also be used to deliver fraudulent solicitations. A "phishing" e-mail is an example of fraudulent spam (Stewart 2004). The "phisher" sends an e-mail to someone pretending to be a legitimate business with an existing relationship with the recipient but seeking to obtain personal information from that recipient that can be used for unlawful purposes such as identity theft or to gain a password that enables unauthorized access to a computer network or data, such as an online bank account.

Spam is more highly regulated in the United States than regular junk mail. Under federal law, Controlling the Assault of Non-Solicited Pornography and Marketing Act of 2003 (CAN-SPAM), deceptive forms of commercial spam are prohibited. For example, it is unlawful to send commercial e-mail ads that disguise the identity of the sender by using a false or misleading e-mail header. CAN-SPAM applies only to commercial spam and does not cover the sending of spam for nonprofit or political purposes. The general rule under CAN-SPAM is that nondeceptive commercial e-mail solicitations may lawfully be sent to recipients without their advance consent as long as the recipients are given the option to "opt-out" of receiving future e-mail solicitations from the sender and have not already made an "opt-out" request. Any spam that includes sexually oriented material must be labeled "SEXUALLY EXPLICIT" in the subject line. There are numerous other technical and disclosure requirements under CAN-SPAM with which companies engaged in advertising by e-mail must comply. CAN-SPAM regulates the sending of commercial solicitations even if sent to only one recipient (i.e., it need not be a bulk or mass e-mail to be covered by CAN-SPAM), so employees engaged in e-mail advertising for a company need to be well aware of the CAN-SPAM Act and its prohibitions. Both civil and criminal penalties are provided under CAN-SPAM (Fingerman 2004). CAN-SPAM supersedes inconsistent state spam laws, but it allows state spam laws to continue to apply to the extent that they provide additional remedies for false and deceptive spam. Other state laws, such as state tort laws, continue to apply after CAN-SPAM and may provide additional remedies for spam victims.

Spyware

Spyware is any software that is placed on a user's computer without his or her knowledge that takes control of the user's computer and/or Internet connections (Report to U.S. Congress 2005). For example, spyware may collect information about a computer user's activities and transmit it to another person. Some spyware is related to advertising and direct marketing and enables advertisers to measure

effective placement of ads on others' Web sites or cause pop-up ads to appear (in this context spyware is called "adware," and is arguably legitimate, at least when the computer user is informed in advance that adware is being installed on their computer). But spyware may be used for more malicious purposes, such as capturing the key strokes of the user (key logging), thus enabling surreptitious collection of passwords and other personal information that may be used for identity theft or other crimes (Report to U.S. Congress 2005). A computer user acquires spyware in various ways, including downloading free or purchased software programs from the Internet or from a disk. Free screen-saving programs and free games have been used to deliver spyware to unknowing computer users. There are commercially available anti-spyware programs that detect and remove spyware.

Several bills have been proposed in Congress to regulate spyware (Report to U.S. Congress 2005). As of this writing, no federal law specifically regulating spyware has been passed; however, some existing laws can be used to fight deceptive uses of spyware and provide remedies for its victims. Both federal and state laws prohibit false or misleading advertising and deceptive business practices. These laws have been used as a basis for lawsuits against those who install spyware on users' computers without adequate notice and consent. For example, the New York Attorney General filed a lawsuit against a company that created and used spyware programs under New York's general business law. Like most states, New York law prohibits companies from creating false advertising and engaging in deceptive business practices (Hines 2005). The lawsuit claims the defendant in the case installed advertising software on home computers without informing the user that it was doing so. The software involved in the case redirected Web addresses, added toolbars, and delivered pop-up ads (Hines 2005).

Unauthorized Access to Computer Networks

Employees using Internet access on the job to access computerized information need to be aware of criminal laws that prohibit unauthorized access to computers or computer networks. The leading federal law on this issue in the United States is the Computer Fraud and Abuse Act of 1984 (Computer Fraud and Abuse Act). State laws also address unauthorized access to computer behavior, commonly referred to as computer hacking and cracking. Under the Computer Fraud and Abuse Act, it is a crime to access a computer without authority and to take data that is restricted or protected. Unauthorized access includes circumventing password or other access restrictions. The law protects financial and credit records, medical records, legal files, and other confidential information in government or private computers.

Policy Implications

As discussed above, spam, spyware, and computer hacking raise data security, online privacy, and network and computer performance issues that should be considered in drafting an e-mail and Internet use policy. The policy

should prohibit company employees from engaging in these types of unlawful behavior and make it clear that unlawful behavior can never be justified as a competitive business practice.

PROTECTING THE PERSONAL DATA OF THIRD PARTIES

This section explores data security and online privacy issues as they relate to protecting the personal data of third parties, such as customers. The same legal protections apply to employees' personal data.

Protecting Customers' Personal Data

The personal data of customers includes information that can be used to individually identify them, such as their names, mailing addresses, e-mail addresses, phone numbers, credit card numbers, and details of their online purchases. Multinational companies that conduct global business (including online business) and/or have employees working outside the United States need to be aware of privacy and data protection laws in other countries. These laws may be far more protective of customers' privacy than U.S. laws. Even if a company has only U.S. employees, multinational companies need to be aware that the same privacy and data protection laws may restrict their ability to collect, use, or disclose personally identifying information (PII) about their customers or other persons who reside outside the United States. See the privacy and data protection discussion in the section on "The Global Perspective." The EU Data Protection Directive and member states' privacy laws mandate a high level of privacy and data protection for the PII of customers as well as employees.

Unlike the laws in many other countries, including the European Union, there is no generally applicable data protection law in the United States that protects the privacy of customers' personal data. However, there are U.S. laws that regulate the privacy of certain kinds of personal data, and these laws may require businesses to protect customers' personal data. Even when no specific statute requires a company to protect customers' personal information, tort or contract law may provide protection and remedies to U.S. customers for privacy and data protection breaches.

Special Issues Related to Collecting Children's Personal Data

The Children's Online Privacy Protection Act of 1998 (COPPA) regulates the online collection of personal data about children. Operators of commercial Web sites or online services that are directed at children under the age of 13 and operators of other Web sites or online services who have actual knowledge that they collect personal information from children online must comply with COPPA. COPPA requires the operators of these types of Web sites or online services to obtain verifiable parental consent before collecting, using, or disclosing personal information from children under age 13. If an employer's business involves operating a Web site or online service that could or does collect personal data from children, its e-mail

and Internet use policy should address compliance with COPPA.

Regulation of Commercial Solicitations, Including Spamming

Employers and employees need to be aware of the laws regulating spam because even one advertising e-mail sent to one customer on behalf of a company may violate U.S. spam laws. In this way, CAN-SPAM differs from foreign spam laws because U.S. law is not limited to bulk or mass unsolicited e-mail (Fingerman 2004). Generally, CAN-SPAM permits businesses to send at least one unsolicited commercial e-mail to someone without his or her advance consent as long as it is truthful and nondeceptive and the recipient has the right to opt out of receiving future solicitations. There is no general exception to CAN-SPAM that allows a business to send commercial e-mail to lists of existing customers without complying with the form requirements in CAN-SPAM, and the business must honor requests by recipients to opt out of receiving further e-mail from the sender. Further, to send a spam message to a cell phone or other wireless device, the sender needs the recipient's consent in advance of sending even one commercial solicitation message.

CAN-SPAM primarily covers false and deceptive commercial e-mail. It prohibits using false or misleading e-mail headers, thus requiring spammers to identify themselves. It also prohibits the sender from misleading the recipient about the contents of the message and requires the sender to use the label "SEXUALLY EXPLICIT" if such material is included in the message. Further, CAN-SPAM requires the sender to include meaningful opt-out mechanisms in e-mail messages, including a physical postal address of the sender, so that recipients can opt out of receiving future e-mails from the sender. The sender must honor opt-out requests within 10 days of receipt. The requirement to honor opt-out requests gives the recipient the right to control whether his or her personal data may be used by the sender for commercial solicitations.

There are both civil and criminal remedies for violation of CAN-SPAM. For example, statutory damages of \$250 per violation up to \$2 million are available for spamming (Fingerman 2004). Further, CAN-SPAM imposes vicarious liability on parties for spam sent by other people, so a business that is promoted in an illegal e-mail by another entity may be liable for violations of CAN-SPAM. Thus, a business must exercise care in selecting advertising services to avoid liability for advertisers' violations of CAN-SPAM on behalf of the business.

PREVENTING EMPLOYEES FROM ENGAGING IN CRIMINAL ACTIVITY

A company's e-mail and Internet policy should also prohibit use of company systems and property for criminal activity including violation of criminal laws. Criminal acts involving spamming, spyware, and unauthorized access to protected computers have already been discussed in previous sections of this chapter and should be covered in the policy. There are many other criminal laws that apply

to employees' use of e-mail or Internet access. For example, criminal laws prohibit acquiring or distributing child pornography and make downloading copyrighted material (without permission of the copyright holders and in excess of "fair use" exceptions) a criminal act.

Workplace Access of Pornography

One survey revealed that nearly half of human resource professionals reported that they have discovered pornography on company computers used by employees (Bachman 2003). Although employees' access of pornography involving adults is generally not a crime, these activities pose serious risk for employers because they may create a hostile work environment, may lead to embarrassing public relations problems, and may constitute a waste of work time when employees view pornography on the job. However, when employees view or distribute pornography involving children using company e-mail and Internet access, they violate criminal laws. A Boeing worker was recently arrested on suspicion of violating laws related to child pornography (Biggs 2003). The Boeing worker was arrested by police after Boeing's security staff told police they suspected the employee had been viewing child pornography via the Internet while at work. Acquiring or distributing child pornography violates state and federal laws that prohibit the exploitation of children. For example, a federal criminal statute prohibits the sexual exploitation of children, including receiving, distributing, or reproducing child pornography (Sexual Exploitation of Children 2005).

Downloading Copyrighted Material Without Permission

With the advent of MP3 technology that enables easy downloading of music, video, and other electronic files, there is an increase in the ability of employees to engage in copyright-infringing activities using the employer's computer systems and Internet access. Infringement can result in civil suits for damages against employers that may be found vicariously liable for copyright infringement by employees. Copyright violations may also lead to criminal penalties under federal copyright laws. The No Electronic Theft Act of 1997 expanded the criminal remedies for copyright violations to include circumstances in which copyright infringements are not motivated by financial gain, as long as the unlawful copies made have a total retail value of more than \$1000 in any 180-day period. Today, even employees who are ignorant of the copyright laws can be criminally responsible for making unauthorized copies of music, videos, or other copyrighted works in the workplace. Likewise, employees who manage to circumvent copyright protection systems that are designed to control access to copyrighted work may violate the Digital Millennium Copyright Act of 1998. Thus, an employer's e-mail and Internet use policy should prohibit "hacking" into copyright protected materials as well as copying or distributing (e.g., forwarding e-mail containing copyright-protect material) without authorization. An effective policy alone may not be enough to deter copyright infringement by employees. Another survey revealed that employees are still swapping

music and other files on peer-to-peer applications at work, despite threats of lawsuits for copyright infringement by the music industry (Reuters 2004). Careful hiring, proper training of employees and supervisors, and monitoring to detect violations are also steps employers should take to prevent copyright violations.

RESERVING THE EMPLOYER'S RIGHT TO CONDUCT ELECTRONIC MONITORING

Electronic monitoring allows an employer to observe what employees do on the job and to review employee communications, including e-mail and Internet activity, and enables employers to capture and review communications that employees consider private. Electronic monitoring also includes the use of computer forensics, a relatively new science and an important advancement in the broader field of electronic monitoring and computer evidence. There are many good business justifications for employers to electronically monitor employees in the workplace. Key reasons for monitoring are to assess worker productivity, to protect company assets from misappropriation, and to ensure compliance with workplace policies. The importance of electronic monitoring to enforcement of the employer's e-mail and Internet use policy is the focus of this section.

The term *electronic monitoring* is used here to encompass three different concepts. First, it includes employer use of electronic devices to review and measure the work performance of employees. For example, an employer may use a computer to retrieve and review an employee's e-mail messages sent to and received from customers to evaluate the employee's performance as a customer service representative. Second, it includes electronic surveillance in the form of an employer's use of electronic devices to observe the actions of employees while employees are not directly engaged in the performance of work duties, or for a purpose other than to measure their work performance. For example, an employer may electronically review an employee's e-mail messages as part of an investigation of a sexual harassment complaint. Third, it includes employer use of computer forensics, the electronic recovery and reconstruction of electronic data after deletion, concealment, or attempted destruction of the data (New Technologies 2006). For example, an employer may use specialized computer forensics software to retrieve or recover e-mail messages stored on the employer's computer hard drive that relate to an investigation of alleged theft of its trade secrets by an employee. Recovery may be possible even if the employee has deleted the messages or reformatted the hard drive.

In countries such as the United States, where electronic workplace monitoring is generally lawful, an e-mail and Internet use policy should reserve the right of the employer to conduct electronic monitoring for the following business reasons:

1. to investigate employee or former employee misconduct
2. to investigate complaints by employees or former employees

3. to respond to litigation discovery requests and requests by government administrative agencies for information and documents

The policy should also reserve the right of the employer to use a broad range of electronic monitoring techniques and technology, including the following:

1. to conduct historical and real-time monitoring
2. to use computer forensics techniques
3. to monitor off-site communications related to the employer's business

By reserving the full panoply of employer rights to conduct electronic monitoring, the employer makes it clear that employees should not have expectations of privacy related to workplace use of e-mail and Internet access. This is a critical component of preventing and defending invasion of privacy claims by employees and others who may be covered by the policy, including former employees and independent contractors.

RESPONDING TO GOVERNMENT REQUESTS FOR ELECTRONIC INFORMATION

Government requests for electronic information may come in a variety of forms. For example, government administrative agencies may request or subpoena information, including electronic documents and other information, in relation to discrimination, workplace safety, environmental, and other complaints. The information requested may include digital documents and electronic communications such as e-mail and Internet chat.

In recent years, because of national security concerns, an important concern for employers is the possibility of being required to respond to government requests for information about their employees or customers that relates to criminal and foreign intelligence investigations. Electronic monitoring of computer systems, including workplace e-mail and Internet access, can be used to discover electronic evidence related to terrorism, computer hacking, and other crimes (King 2003, Electronic monitoring). However, there are important privacy issues for employees that relate to employer monitoring for national security concerns (King 2003, Electronic monitoring). In October 2001, the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism Act (USA PATRIOT Act 2001) amended provisions of the ECPA that prohibit interception of oral, wire, and electronic communications and restrict access to stored wire and electronic communications. As a result of the USA PATRIOT Act's amendments to these federal laws, employers may likely be asked, and in some cases compelled, to provide private information about employees and former employees to law enforcement and other government agencies (King 2003, Electronic monitoring). The employers' expanded legal obligations include the possibility of employers receiving government requests to produce information about a former or current employee

in conjunction with a criminal investigation or government intelligence surveillance of potential terrorism activities. Government orders and requests can take various forms, including search warrants, court wiretap orders, pen-register and trap and trace orders, and subpoenas. The expanded employer legal obligations under the USA PATRIOT Act are essentially obligations to engage in electronic monitoring and/or to produce electronic communications, raising workplace privacy concerns. In some cases, the government order to conduct electronic monitoring of an employer's electronic communications system requires the employer to keep its participation secret even from the employee who is being monitored (King 2003, Electronic monitoring).

For the above-listed reasons, an employer's e-mail and Internet policy should anticipate that the employer may be required to monitor its system and to secretly produce electronic communications and documents to the government under government order. Accordingly, an employer should not promise that it will notify employees if their e-mail or Internet access is disclosed to the government—current federal law may make it unlawful to keep this promise.

RESERVING THE EMPLOYER'S RIGHT TO DISCIPLINE EMPLOYEES FOR MISUSE

An important component of an e-mail and Internet use policy is to reserve the employer's right to discipline employees for violation of the policy. The policy should provide employees with a warning that violations of the policy may lead to discipline up to and including termination from employment, thus serving to notify employees of the consequences of violating the policy. Certainly some misconduct or criminal activity engaged in by employees in violation of the employer's e-mail and Internet use policy may lead to immediate discharge. For example, an employee found to have distributed child pornography using the employer's computer system may face criminal prosecution as well as discipline for violating the employer's policy. Such a policy violation may clearly merit discharge from employment. However, other violations of the employer's policy may appear less serious and merit discipline short of discharge but that is designed to punish the offender and to set an example for other employees that may deter similar policy violations. For example, an employee found to have engaged in excessive personal, but lawful, use of the employer's e-mail or Internet access may be warned, placed on probation, or otherwise disciplined for the policy infraction, but would rarely be discharged for a first offense. A well-drafted e-mail and Internet use policy will reserve the right of the employer to discipline employees appropriately under the circumstances.

In countries where employees have fundamental rights of privacy even in private-sector workplaces, discipline of employees who violate their employers' e-mail and Internet use policies may be restricted to protect employees' privacy rights. For example, in *Onuf v. Nikon* (2001), the French Supreme Court considered the discharge of an employee for alleged improper use of work time. Evidence of the employee's misconduct included e-mail messages he

had sent at work and marked "personal." The French court held the employer was not permitted to read the employee's personal e-mail and that "doing so is a violation of the fundamental right of secrecy in one's private correspondence even when that correspondence is conducted via an employer's e-mail system and in violation of company policy" (Finken 2000, 313 [quoting the French court]).

ADDITIONAL TIPS ON COMPLYING WITH U.S. EMPLOYMENT LAWS

In addition to the key legal concerns discussed earlier in this chapter, including employees' privacy, there are many other legal issues that relate to drafting and enforcing e-mail and Internet use policies. This section addresses some of the other legal concerns related to drafting and enforcing e-mail and Internet use policies for employees in the United States. Similar legal concerns may apply to drafting policies covering non-U.S. employees, and should be explored with local legal counsel.

Discrimination and Harassment Concerns

An important component of an e-mail and Internet use policy is to prohibit unlawful discrimination and harassment. The risk that employees will harass or make discriminatory statements using e-mail or in an Internet chat room is significant, and has been the focus of several lawsuits against employers. In *Blakey v. Cont'l Airlines, Inc.* (2000), an airline captain complained of sexual harassment and a hostile work environment after coworkers placed derogatory messages referring to her gender on an electronic bulletin board that the employer provided for its employees' use. The fact that the electronic bulletin board was operated by CompuServe, a third-party provider, was not a good defense for the employer—an appellate court ordered the trial court to consider whether the electronic bulletin board was so closely related to the workplace that it should be regarded as part of the workplace.

An employer's policy may also be a proactive tool to avoid liability for harassment and discrimination if it prohibits harassment or discrimination on the part of coworkers and the employer takes prompt remedial action to remedy any harassment once a complaint is made. For example, in *Schwenn v. Anheuser-Busch, Inc.* (1998), an employee lost a sexual harassment suit based on receipt of sexually harassing e-mail from coworkers on her office computer. Shortly after she complained, Anheuser-Busch investigated the complaint and took corrective action—it held two employee meetings to tell employees that its company sexual harassment policy prohibited harassment via e-mail and advised employees it would monitor e-mail messages and would discipline or discharge employees who violated the policies. In another case, an employee lost a lawsuit claiming that the employer negligently allowed employees to use the company e-mail system to send racially harassing e-mail (*Daniels v. Worldcom Corp.* 1998). The employer in *Daniels* was found not to have been negligent because, upon learning of misuse of its e-mail system, it organized employee meetings to discuss proper use of the e-mail system and disciplined the employees who had improperly used it.

All forms of unlawful discrimination and harassment prohibited by state and federal laws applicable to the employer should be prohibited in the employer's e-mail and Internet use policy. Actually, unlawful harassment is a form of unlawful discrimination. For example, unwanted derogatory comments about a person's gender or pregnancy, sexual jokes, and comments of a sexual nature are forms of sex discrimination that are prohibited by law when they generate a hostile work environment. Federal law prohibits discrimination and harassment in the workplace on the basis of gender or sex, race or color, national origin, religion, age, and disability (Title VII of the Civil Rights Act of 1964; the Age Discrimination in Employment Act of 1967; the Americans with Disabilities Act of 1990). An employer may also be required to prohibit other forms of discrimination and harassment, such as sexual orientation discrimination or harassment, because they are prohibited by state law (e.g., *Tanner v. OHSU* 1998), or because the employer has adopted a voluntary policy to prohibit such forms of harassment.

Disability and Medical Confidentiality Concerns

The primary source of federal law that requires employers to protect the confidentiality of medical information related to employees is the Americans with Disabilities Act of 1990 (ADA). The ADA applies to all employment practices and policies of employers with more than fifteen employees, including workplace e-mail and Internet use policies. The ADA's medical confidentiality rules protect all applicants and employees of a covered employer, even if the individual does not have a disability as defined by the ADA. It is likely, however, that the employer's liability under the ADA is limited by the employee's need to show he or she has an actual disability, a record of a disability, or has been regarded as having a disability by the employer in order to recover damages (*Sutton v. United Airlines, Inc.* 1999). The ADA requires employers to keep disability-related information confidential. In essence, the ADA prohibits companies from disclosing information about applicants' and employees' medical conditions, physical or mental impairments, and medical treatments to anyone inside or outside the company, except when permitted for specified purposes set out in the ADA (United States Equal Employment Opportunity Commission 2000).

The ADA also limits the inquiries that an employer may lawfully make about an applicant's or an employee's medical condition or disability. For example, prior to making a conditional offer of employment, an employer is prohibited from asking job applicants any questions that would reveal a physical or mental disability. In the pre-employment stage, after making a conditional offer of employment, the employer is free to delve into an applicant's medical history and medical condition, although the employer may only use such information for job-related reasons. After employment begins, an employer is prohibited from asking employees any questions about their medical conditions or disabilities unless the questions are job-related and necessary. Details of an employee's medical treatment or condition are rarely job-related or necessary, and the ADA generally prohibits employers from prying

into the employee's medical condition to the extent the employer is seeking disability-related information. This rule generally limits the employer from seeking employee medical information beyond assessing the employee's ability to perform job functions, need for accommodation, or need for time away from work. Family and medical leave laws also restrict the amount of information that an employer may request from the employee or the employee's doctor to substantiate an employee's leave request and require employers to keep an employee's medical reasons for taking family and medical leave confidential (see, e.g., Federal Family and Medical Leave Act of 1993).

An employer's e-mail and Internet use policy should prohibit uses of the employer's systems that would violate disability discrimination laws. In the policy or training related to the policy, employers should train supervisors on appropriate use of e-mail in light of the ADA and family and medical leave laws. Such training should include instruction not to use e-mail to ask applicants or employees for "disability-related" information prohibited by the ADA or for medical information that would violate family and medical leave laws. Employers also need to be cognizant that the digital form of electronic communications creates significant additional litigation risk for employers. For example, e-mail records of improper disability-related inquiries may exist in the employer's computer systems and files for lengthy periods. These electronic records may also be recoverable using computer forensics techniques. Electronic records may provide damaging evidence of ADA violations in disability discrimination or family and medical leave claims and lawsuits.

Another concern is whether e-mail or Internet communications from applicants or employees contain confidential medical information. The ADA or family and medical leave laws require employers to keep this type of information in separate confidential files and not to disclose it except as authorized by law. There is the potential for the employer to violate medical confidentiality laws whenever employees communicate with their supervisors about their medical conditions. For example, a supervisor may send an e-mail to ask the employee for information that the employer is not entitled to request, such as details about an employee's medical diagnosis or prognosis that are unnecessary to determine whether the employee is currently able to do his or her job or to process a request for a family or medical leave. Or an employee may voluntarily provide confidential medical information to a supervisor by e-mail, but the supervisor may unlawfully forward the e-mail message containing confidential medical information to coworkers or clients who are not entitled to have access to the information. The employer should also be concerned with the security of electronically stored e-mail and Internet communications, particularly the need to protect confidential medical information from snooping coworkers or hackers.

Health care providers, including self-insured employers who provide medical insurance directly for their employees, should also be aware of the medical confidentiality rules of the Health Insurance Portability and Accountability Act of 1996 (HIPAA). Administrative rules interpreting HIPAA require privacy for customers of health care providers including employees covered by self-insured plans

(HIPAA Privacy Regulations 2005). The HIPAA Privacy Regulations apply when a health care provider transmits health care information electronically. Under these regulations, the data subject is required to give permission for use or disclosure of health care data unless a statutory exclusion applies (Manny 2003).

Federal Labor Law Protections

Most employees working for private businesses have some protections under Section 7 of the federal National Labor Relations Act of 1935 (Section 7 and NLRA), even if they are not represented by a union (King 2003, Labor law for managers). For example, if nonunion or union-represented employees in private-sector workplaces communicate with each other about their workplaces, including discussions about wages or other terms and conditions of employment, Section 7 of the NLRA may protect their communications from employer interference as “protected concerted activity” (King 2003, Labor law for managers). If an employer’s e-mail and Internet use policy is broadly worded to prohibit employees from engaging in Section 7 activities, it will violate the NLRA. A policy that violates Section 7 of the NLRA is not enforceable and gives employees the right to file unfair labor practices charges against the employer with the National Labor Relations Board (NLRB). Employees are entitled to seek remedies such as back pay and reinstatement if they are disciplined or discharged under policies that violate the NLRA. Employment policies such as confidentiality policies and wage-secrecy policies also are unenforceable under Section 7 if they are too broadly worded. For example, workplace policies that prohibit nonsupervisory employees from talking with each other about their wages generally violate Section 7. Therefore, e-mail or Internet use policies that include overly broad confidentiality or wage-secrecy provisions may violate Section 7.

An issue that is hotly debated is whether an employer’s e-mail and Internet use policy may prohibit all nonbusiness use of the employer’s systems, even use by employees to communicate about matters that would be protected by Section 7 of the NLRA. Current federal labor law seems to support the view that the employer may prohibit employees from engaging in *all* personal use of its e-mail or Internet access. In other words, an employer may have a business-use-only e-mail and Internet access policy, providing it enforces the policy in a nondiscriminatory way and prohibits all personal use, not just use for union-related matters or Section 7 protected matters (King 2003, Labor law for managers). However, if the employer’s e-mail and Internet use policy permits some personal use of the employer’s systems by employees, it must also permit employees to use the employer’s systems and equipment to discuss matters that fall under the umbrella of “protected concerted activity.” Protected concerted activity includes discussion between employees of union matters, wages, or other matters of mutual concern to employees.

Employers may have valid business reasons to limit personal e-mail or Internet use by employees, even when the employer’s policy permits reasonable personal use. For example, if the employer can show that certain types of personal e-mail or Internet use by employees unduly

burden its systems, the employer may restrict the personal use for valid business reasons. Mass e-mails sent by employees that overburden an employer’s computer systems and personal e-mails that expose the employer’s systems to computer viruses are valid business reasons for an employer to limit employees’ personal use of a company’s systems. Also, even if an employer permits employees to make reasonable personal use of its e-mail and Internet systems, it need not permit employees to use work time for this purpose. The employer has a legitimate right to prevent loss of work time by employees sending and receiving e-mails for personal reasons (King 2003, Labor law for managers).

For a discussion of bargaining and enforcing a policy covering union employees, see the section on “Special Issues Related to Union-Represented Employees,” found later in this chapter.

Respecting Constitutional Rights

Generally, employers in the private sector may adopt e-mail and Internet policies without worrying about federal or state constitutional restrictions because private-sector employment practices are not covered by the U.S. Constitution or by most state constitutions (Burgunder 2004). A few states have constitutions that protect the privacy of employees in private-sector workplaces (Safon 2000). California is one of these states (California Constitution 2005). For issues of constitutional law that relate to drafting policies for government employees, see the discussion of this topic in the section on “Special Issues Related to Government Employees,” found later in this chapter.

Respecting Employment Contracts

Although at-will employment is common in private-sector employment in the United States, it is not the only type of employment relationship that is possible. Union-represented and government employees typically are not at-will employees, but rather have greater contractual rights related to their employment (see the next section). But even employees in private-sector workplaces may be covered by employment contracts that give them contractual rights that are greater than at-will employment, such as a right to be discharged only for just cause (Cottone 2002; Leonard 1988). Such employees have express or implied contractual rights that are found in their individual employment contracts, including implied contractual rights that arise from employer policies, whether written or not. Whether employees have express or implied employment rights greater than those of an at-will employee depends on whether a court, interpreting the employment contract, finds the employer’s promises, which may be in the form of a policy, are enforceable and confer greater rights than at-will employment. For example, promises made in workplace policies established by employers may be enforced as “implied contracts” by the courts (*Toussaint v. Blue Cross & Blue Shield of Michigan* 1980; *Berube v. Fashion Centre Ltd.* 1989). In *Toussaint* and *Berube*, written disciplinary policies promising not to

discharge the employees except for cause gave employees rights to sue their employers for breach of contract when their employment was terminated. Employers who make oral or written promises to employees of privacy and data protection related to e-mail and Internet use can expect to have those promises enforced. Discipline of employees or termination of their employment for reasons that violate implied contracts may be a breach of those contracts and a violation of the legal rights of employees, and gives employees the right to recover damages or perhaps seek reinstatement. Exercising caution as a policy drafter or in other communications with employees is essential to avoid making unintended but binding contractual promises to employees.

Often the critical policy-drafting issue for employers is to avoid inadvertently creating implied legal rights that employees would not otherwise have under existing laws. To illustrate, if an employer's e-mail and Internet use policy promises employees that their personal communications will not be read by the employer, the policy may create a contractual promise of personal privacy in the workplace—a privacy right that at-will employees in U.S. workforces do not otherwise have (King, 2003, Electronic monitoring). If the employer then violates its own policy by reading the personal e-mail of employees and terminates employees for the contents of the e-mail, the employees may be able to successfully argue in court that their termination is a breach of an implied employment contract.

Although implied contracts have been enforced in employment situations, employees have not prevailed on this claim in any reported case that relates to e-mail and Internet access. One court even disregarded an oral promise of privacy made by an employer, finding the promise created no privacy rights or, even if it did, the employer acted reasonably in the circumstances. In this case, the employer suspended the employee for investigation of misconduct. The employer then successfully bypassed a password set by the employee that protected his personal files stored on the employer's computers, read the files, discovered evidence of misconduct, and then terminated his employment for misconduct (*McLaren v. Microsoft Corporation*, 1999). Employees have, however, prevailed in similar cases involving implied contracts based on other types of workplace policies. For example, in *Woolley v. Hoffmann-La Roche, Inc.* (1985), express and implied promises in the defendant's employment manual created an employment contract under which an employee could not be fired at will, but rather only for cause, and then only after the procedures outlined in the manual were followed. For this reason, employers should be careful not to make promises in e-mail and Internet use policies that they are not prepared to keep. It is also a good idea to add a disclaimer in a policy, or in a handbook containing policies, to make it clear that the employer's policy does not create express or implied contractual rights for employees (*Federal Express Corp. v. Deutschmann* 1993). In *Federal Express* the court held that an employee handbook expressly stating that employment at the company was at will and disclaiming any other contractual employment rights was binding and precluded recovery of damages for breach of contract by an employee.

Special Issues Related to Union-Represented Employees

In workplaces where employees are represented by a labor union, the employer generally must bargain with the employees' union representative before introducing a new or a substantially revised policy regarding employees' use of informational technologies when employees may be disciplined under the policy (*King Soopers, Inc.* 2003). This is because imposition of a new or substantially revised workplace policy that establishes a basis for employee discipline is a mandatory subject of bargaining under the National Labor Relations Act. Although there is little definitive guidance on the topic, imposition of a new e-mail or Internet policy covering union employees must be bargained if employees may be disciplined for failing to follow the policy (Lieber 1998). A requirement to bargain with the union does not require the employer and union to agree on the terms of the policy. However, the employer is required to bargain in good faith about the effects of imposing the policy until a bargaining impasse is reached—only then may the employer unilaterally impose its proposed workplace policy. An employer may also have an obligation to bargain with the union over imposition of electronic monitoring or other surveillance practices or policies that are designed to detect violations of the e-mail and Internet policy. For example, an employer was required to bargain with union representatives over the imposition of new package-inspection practices designed to prevent employee theft (*Edgar P. Benjamin Healthcare Center* 1996). So, by analogy, an employer may be required to bargain about electronic monitoring practices designed to prevent employee abuse of its computer systems and violations of its e-mail and Internet use policy.

If an employer implements a workplace policy without bargaining with the union or obtaining the union's waiver of its right to bargain, either the union or employees may file an unfair labor practice charge with the NLRB. Also, even if the policy is lawfully implemented, when disputes about e-mail and Internet use or employer monitoring arise, employers may have obligations under collective bargaining agreements to arbitrate these disputes. Such disputes may include disputes about employee discipline for violating the e-mail and Internet use policy or disputes about whether the employer's electronic monitoring violates the collective-bargaining agreement.

Special Issues Related to Government Employees

Government employees may have constitutional rights to privacy under federal or state laws that employees in the private sector generally do not have, including a Fourth Amendment right to be free from unreasonable searches and seizures by their government employer (*O'Connor v. Ortega* 1987). However, even when a constitutional right to privacy claim may be made, employers have generally prevailed on invasion of privacy claims. In *Kelleher v. City of Reading* (2002), a city employee lost a claim for invasion of privacy against the city for allegedly publicizing her e-mail and other purportedly private information relating to her suspension by the city. And in *U.S. v. Simmons*

(2000), the federal government used electronic monitoring to examine the records of Web sites visited by a federal employee and then examined files saved on his computer. The court recognized that public-sector employees may have constitutional or statutory privacy rights in e-mail communications in some circumstances. However, the court said this employee did not have an objectively reasonable expectation of privacy in electronic communications made in the workplace in light of the employer's monitoring policy. The employer's policy specified the types of data that would be monitored, including e-mail, Internet, and electronic file transfers, and specified the ways in which the data would be retrieved, including audit and inspection. However, even if public employees' e-mail messages are public records that a public employer may monitor, courts have issued injunctions to prevent public disclosure of the contents of personal e-mail as personal information (*Tiberino v. Spokane County* 2000). Although most constitutional invasion of privacy claims relate to public employees, states such as California have also extended state constitutional rights to privacy to private-sector employees (Safon 2000; California Constitution 2005).

A number of important issues have been discussed in this chapter that relate to drafting an effective e-mail and Internet use policy. A summary of some of these issues is provided in Table 1. Table 1 also includes drafting suggestions for policies covering at-will employees working in private sector, nonunion workplaces in the United States.

CONCLUSION

The reassuring news for employers about drafting e-mail and Internet use policies is that well-drafted policies educate employees about the proper ways to use e-mail and the Internet, help protect employers' property and trade secrets, and help prevent expensive lawsuits related to misuse of the employers' systems. One of the challenges for employers is to comply with the multitude of laws that protect employee rights in this situation. It is true that private-sector employers in the United States have the most latitude to draft policies that do not expand employee privacy and other legal rights, yet reserve employer rights to monitor and enforce their policies. Multinational companies with employees and customers in the European Union and other countries that have adopted privacy laws similar to those of the European Union face the greatest challenges as they seek to comply with laws protecting the privacy of personal information and electronic communications, while preserving employer rights to monitor their systems and enforce their policies.

A key challenge for policy drafters is to keep abreast of the developments in laws that protect employee rights in the workplace and regulate improper uses of e-mail and Internet access by company employees. Because business is increasingly global, drafting a company policy for e-mail and Internet use that is consistent with the laws in the countries where the company operates is a key challenge for multinational companies. Countries other than those in the European Union are following the lead of the European Union in establishing workplace privacy and data protection rights for employees related to e-mail and Internet communications. In addition, employees commonly use

the personal data of others, including customers and employees, in the process of using e-mail and Internet access on the job. In many countries, including the United States and EU member countries, the use of customers' personal data in conjunction with the use of e-mail and Internet access is increasingly regulated. So, employees' using their employers' e-mail and Internet access to do their jobs may run afoul of civil and criminal laws such as those addressing spam or communications with children.

A well-drafted e-mail and Internet use policy also needs to be effectively communicated to users who will be required to follow the policy. However, having a policy is no substitute for good management practices and consistent enforcement of the policy. Finally, all e-mail and Internet use policies should be reviewed by the company's legal counsel. Although this chapter provides much insight into the legal issues of which policy drafters and enforcers should be aware, it does not provide specific legal advice for any company related to its e-mail and Internet use policy and is not a substitute for consulting legal counsel.

GLOSSARY

At-Will Employment: The traditional view of the employment relationship in the United States, in which either the employee or the employer may terminate the employment at any time, without advance notice, and for any lawful reason. There are many exceptions to at-will employment that have been created in contracts, statutes, constitutions, or in some cases by courts. The major exceptions include prohibitions on the termination of an at-will employee for reasons that violate public policy (prohibiting termination for serving on jury duty, filing workers' compensation claims, etc.); for reasons that violate discrimination statutes (prohibiting race, color, sex, religion, national origin, age, disability, pregnancy, harassment, and other forms of unlawful discrimination); for engaging in protected concerted activity under federal or state labor laws; for reporting unsafe working conditions; and for reporting criminal or other wrongful activity in the workplace (whistle-blowing). Employees in the private sector are presumed to be at will in the United States unless they are covered by an employment contract that promises employees greater protection from discipline or termination, such as a promise to be terminated only for "just cause." Union-represented employees covered by collective bargaining agreements generally have a right to be disciplined or terminated only for just cause, and thus are not at-will employees.

Computer Forensics: The electronic recovery and reconstruction of electronic data after deletion, concealment, or attempted destruction of the data, generally from the hard drive of a computer.

Contract: An agreement between two or more parties creating obligations that a court will enforce. The agreement may be oral or written and may also be implied from the parties' conduct rather than their words. For example, an implied employment contract may be based on an employment handbook or employment policy that has been communicated to employees.

Copyright: A property right of an author of an original work that has been fixed in a tangible medium, including literary, musical, artistic, photographic, or film works. The holder of a copyright has the exclusive right to reproduce, distribute, perform, and display the work.

Disabled Person: A person is protected by federal disability laws if that person has a physical or mental impairment that substantially limits one or more major life activities, has a record of a substantially limiting physical or mental impairment, or is perceived by others as having such impairment. Under federal disability laws, all applicants and employees are entitled to medical confidentiality from their employers even if they are not disabled.

Disclaimer: A statement repudiating or renouncing the legal rights of another. For example, an employer may include a disclaimer in an employment policy or handbook to disavow the creation of any contractual rights on the part of employees and to attempt to retain an at-will employment relationship.

Electronic Workplace Monitoring: Use of electronic devices and/or computer software to measure or observe the work performance of employees, to conduct electronic surveillance of the workplace, including observation of the actions and communications of others, and the use of computer forensics to recover or reconstruct evidence of the actions or communications of employees and others related to the workplace.

European Data Protection Directive: Requires member states of the European Union to enact national laws consistent with the European Data Protection Directive (Directive 95/46/EC of the European Parliament and of the Council of 24 October 1995) to protect the privacy of personal data when it is processed by another person or company, including an employer. Requires that processing of personal data be fair and lawful and that data be collected for legitimate purposes, be relevant, be accurate, and be kept in a form that permits identification of data subjects for no longer than is necessary for the purposes of the collection of the data. Provides that data subjects are entitled to access data about themselves and have rights to correct data about themselves. Applies to both consumer and workplace data protection issues. Restricts transfer of personal data about European residents to countries outside the European Union that have privacy laws that fail to provide an adequate level of data protection.

Fair Use: An exception under the U.S. Copyright Act that allows one who does not own a copyright to make limited "fair use" of the copyrighted work for purposes such as criticism, comment, news reporting, teaching, scholarship, or research without being liable for copyright infringement. Fair use is primarily an affirmative defense to a claim of copyright infringement. Qualification for the affirmative defense is determined by courts on a case-by-case basis and depends on: (1) the purpose and character of the use, including whether the use is of a commercial nature or for nonprofit, educational purposes; (2) the nature of the copyrighted work; (3) the amount and substantiality of the portion of the copyrighted work that is used in relation to the

whole of the copyrighted work; and (4) the effect of the use on the potential market for or the value of the copyrighted work.

Family and Medical Leave: A form of protected leave from employment that is protected by federal and some state laws. The leave is available for an employee's serious health condition, for the birth or adoption of a child, and for the serious health condition of a family member, defined as a parent, spouse, or child. A person is not required to be disabled within the meaning of federal or state law to qualify for family and medical leave. Persons on family and medical leave are entitled to medical confidentiality from their employers.

Hostile Work Environment: A form of harassment prohibited by U.S. federal and state discrimination laws. A hostile work environment is unlawful when it is based on an employee's sex (or gender), race, color, national origin, religion, age, or disability (prohibited classifications). Although federal laws do not protect employees from sexual orientation or marital discrimination, state and local laws may prohibit harassment and discrimination for these reasons. Words or conduct of coworkers, supervisors, managers, or third parties that occurs in or is associated with the workplace are unlawful discrimination when the words or conduct are based on one or more of the prohibited classifications, are unwelcome, and are sufficiently serious or pervasive.

Noncompetition Agreements: An agreement between an employer and an employee or an independent contractor that restricts the ability of the employee or independent contractor from working for a competitor and/or competing directly through his own business with his employer. Such agreements are generally disfavored under the law because they restrict competition. However, depending on state law, noncompetition agreements may be enforceable if reasonable. Factors considered by courts in determining reasonableness include the scope of the noncompetition activity covered by the agreement, the term of the agreement, and the size of the geographic area in which noncompetition is restricted.

Nondisclosure Agreements: An agreement between an employer and an employee or an independent contractor that restricts the ability of the employee or independent contractor to disclose confidential or proprietary information of the employer. Such agreements are likely to be enforceable under state law and are consistent with the fiduciary duty that an agent owes a principal to be loyal to the principal in carrying out his responsibilities. This duty may extend beyond termination of the employment and/or the agency relationship.

Tort: The breach of a legal duty established by law that causes injury or damage to another. This is a civil wrong that does not arise from a contract. One who violates a civil duty and injures another may be required to pay damages to the person injured. Examples of torts include defamation, assault, battery, wrongful interference by a third party with a contractual relationship, and invasion of privacy.

Trade Secret: A formula, process, device, or other business information that is kept confidential to maintain a competitive advantage.

INTRODUCTION

Network management, in general, is a service that uses a variety of protocols, tools, applications, and devices to assist human network managers in monitoring and controlling the proper network resources, both hardware and software, to address service needs and the network objectives. This includes performing functions such as initial network planning, frequency allocation, predetermined traffic routing to support load balancing, cryptographic key distribution authorization, configuration management, fault management, security management, performance management, bandwidth management, and accounting management.

When transmission control protocol/Internet protocol (TCP/IP) was developed, little thought was given to network management. Prior to the 1980s, the practice of network management was largely proprietary because of the high cost of development. The rapid movement in the 1980s toward larger and more complex networks caused a significant diffusion of network management technologies. The starting point in providing specific network management tools was in November 1987, when simple gateway monitoring protocol (SGMP) was issued. In early 1988, the Internet Architecture Board (IAB) approved a simple network management protocol (SNMP) as a short-term solution for network management. Standards like SNMP and common management information protocol (CMIP) paved the way for standardized network management and the development of innovative network management tools and applications.

However, these protocols were not designed for wireless networks. The wireless-specific mobility management, including handoff management and location management, were not addressed in these protocols.

Network management system (NMS) refers to a collection of applications that enable network components to

be monitored and controlled. In general, network management systems have the basic architecture shown in Figure 1. The architecture consists of two key elements: a managing device, called a “management station,” or a “manager,” and the managed devices, called “management agents,” or simply “agents.” A management station serves as the interface between the human network manager and the network management system. It is also the platform for management applications to perform management functions through interactions with the management agents. The management agent responds to the requests from the management station and also provides the management station with unsolicited information.

Given the diversity of managed elements, such as routers, bridges, switches, hubs, and so on, and the wide variety of operating systems and programming interfaces, a management protocol is critical for the management station to communicate with the management agents effectively. SNMP and CMIP are two well-known network management protocols. A network management system is generally described using the open system interconnection (OSI) network management model. As an OSI network management protocol, CMIP was proposed as a replacement for the simple but less sophisticated SNMP; however, it has not been widely adopted. For this reason, we will focus in this chapter on SNMP.

OSI Network Management Model

The OSI network management comprises four major models:

- The **organization model** defines the manager, agent, and managed object. It describes the components of a network management system, the components’ functions, and its infrastructure.

Figure 1: Typical network management architecture (Cisco Systems 2002)

- The **information model** is concerned with the information structure and storage. It specifies the information base used to describe the managed objects and their relationships. The structure of management information (SMI) defines the syntax and semantics of management information stored in the management information base (MIB). The MIB is used by both the agent process and the manager process for management information exchange and storage.
- The **communication model** deals with the way information is exchanged between the agent and the manager and between the managers. There are three key elements in the communication model: the transport protocol, the application protocol, and the actual message to be communicated.
- The **functional model** comprises five functional areas of network management, which are discussed in more detail in the next section.

Network Management Layers

Two protocol architectures have served as the bases for the development of interoperable communications standards: the International Organization for Standardization (ISO) OSI reference model and the TCP/IP reference

model, which are compared in Figure 2 (Tanenbaum 2003). The OSI reference model was developed based on the premise that different layers of the protocol provide different services and functions. It provides a conceptual framework for communications among different network elements. The OSI model has seven layers. Network communication occurs at different layers, from the application layer to the physical layer; however, each layer can communicate only with its adjacent layers. The primary functions and services of the OSI layers are described in Table 1.

The OSI and TCP/IP reference models have much in common. Both are based on the concept of a stack of independent protocols. Also, the functionality of the corresponding layers is roughly similar.

However, differences do exist between the two reference models. The concepts that are central to the OSI model include service, interface, and protocol. The OSI reference model makes the distinction among these three concepts explicit. The TCP/IP model, however, does not clearly distinguish among these three concepts. As a consequence, the protocols in the OSI model are better hidden than in the TCP/IP model and can be replaced relatively easily as the technology changes. The OSI model was devised before the corresponding protocols were invented;

Figure 2: The OSI and TCP/IP reference models

Table 1: OSI layers and functions

Layer	Functions
Application	Provides the user application process with access to OSI facilities
Presentation	- Responsible for data representation, data compression, and data encryption and decryption - Ensures communication between systems with different data representations - Allows the application layer to access the session layer services
Session	- Allows users on different machines to establish sessions between them - Establishes and maintains connections between processes, and data-transfer services
Transport	- Provides reliable, transparent data transfer between end systems, or hosts - Provides end-to-end error recovery and flow control - Multiplexes and de-multiplexes messages from applications
Network	- Establishes, maintains, and terminates connections between end systems - Builds end-to-end route through the network
Data Link	- Composed of two sublayers: logical link control (LLC) and media access control (MAC) - Provides a well-defined service interface to the network layer - Deals with transmission errors - Regulates data flow
Physical	- Handles the interface to the communication medium - Deals with various medium characteristics

therefore, it is not biased toward one particular set of protocols, which makes it quite general. With TCP/IP, the reverse is true: the protocols came first, and the model was really just a description of the existing protocols. Consequently, this model does not fit any other protocol stacks (Tanenbaum 2003).

The rest of the chapter is organized as follows. In the next section, ISO network management functions are briefly described. Network management protocols are discussed in the subsequent section. This is followed by a section on network management tools and then by a section on policy-based network management, followed by our conclusions.

ISO NETWORK MANAGEMENT FUNCTIONS

To ensure rapid and consistent progress on network management functions, including operations, administration, and maintenance (OAM), ISO has grouped the management functions into five areas: (1) configuration management, (2) fault management, (3) security management, (4) accounting management, and (5) performance management. The ISO classification has gained broad acceptance for both standardized and proprietary network management systems. A description of each management function is provided in the following subsections.

Configuration Management

Configuration management is concerned with initializing a network, provisioning the network resources and services, and monitoring and controlling the network.

More specifically, the responsibilities of configuration management include setting, maintaining, adding to, and updating the relationship among components and the status of the components during network operation.

Configuration management consists of both device configuration and network configuration. Device configuration can be performed either locally or remotely. Automated network configuration, such as dynamic host configuration protocol (DHCP) and domain name services (DNS), plays a key role in network management.

Fault Management

Fault management involves detection, isolation, and correction of abnormal operations that may cause the failure of the OSI network. The major goal of fault management is to ensure that the network is always available and that when a fault occurs, it can be fixed as rapidly as possible.

Faults should be distinct from errors. An error is generally a single event, whereas a fault is an abnormal condition that requires management attention to fix. For example, the physical communication line cut is a fault, while a single-bit error on a communication line is an error.

Security Management

Security management protects the networks and systems from unauthorized access and security attacks. The mechanisms for security management include authentication, encryption, and authorization. Security management is also concerned with generation, distribution, and storage of encryption keys as well as other security-related information. Security management may include

security systems such as firewalls and intrusion-detection systems that provide real-time event monitoring and event logging.

Accounting Management

Accounting management enables the charge for the use of managed objects to be measured and the cost for such use to be determined. The measure may include the resources consumed, the facilities used to collect accounting data and set billing parameters for the services used by customers, the maintenance of the databases used for billing purposes, and the preparation of resource usage and billing reports.

Performance Management

Performance management is concerned with evaluating and reporting the behavior and the effectiveness of the managed network objects. A network monitoring system can measure and display the status of the network, such as gathering the statistical information on traffic volume, network availability, response times, and throughput.

NETWORK MANAGEMENT PROTOCOLS

In this section, different versions of SNMP and RMON will be introduced. SNMP is the most widely used data network management protocol. Most of the network components used in enterprise network systems have built-in network agents that can respond to an SNMP network management system. This enables the new components to be monitored automatically. Remote network monitoring is, on the other hand, the most important addition to the basic set of SNMP standards. It defines a remote network monitoring MIB that supplements MIB-II and provides the network manager with vital information about the internetwork.

SNMP

The objective of network management is to build a single protocol that manages both OSI and TCP/IP networks. Based on this goal, SNMP, or SNMPv1 (Case et al. 1990; McCloghrie and Rose 1991; Rose and McCloghrie 1990), was first recommended as an interim set of specifications for use as the basis of common network management throughout the system, whereas the ISO CMIP over TCP/IP (CMOT) was recommended as the long-term solution (Cerf 1988, 1989).

SNMP consists of three specifications: the SMI, which describes how managed objects contained in the MIB are defined; the MIB, which describes the managed objects contained in the MIB; and the SNMP itself, which defines the protocol used to manage these objects.

SNMP Architecture

The model of network management that is used for TCP/IP network management includes the following key elements:

- **Management station:** hosts the network management applications.
- **Management agent:** provides information contained in the MIB to management applications and accepts control information from the management station.
- **Management information base:** defines the information that can be collected and controlled by the management application.
- **Network management protocol:** defines the protocol used to link the management station and the management agents.

The architecture of SNMP, shown in Figure 3, demonstrates the key elements of a network management

Figure 3: SNMP network management architecture

Version	Community Name	SNMP PDU
---------	----------------	----------

(a) SNMP message

PDU Type	RequestID	ErrorStatus	ErrorIndex	VariableBindings				
				Name 1	Value 1	...	Name N	Value N

(b) Get/Set Type of PDUs

PDU Type	Enterprise	Agent-Address	Generic-Trap	Specific-Trap	Timestamp	VariableBindings				
						Name 1	Value 1	...	Name N	Value N

(c) Trap PDUs

Figure 4: SNMP message formats

environment. SNMP is designed to be a simple message-based application-layer protocol. The manager process achieves network management using SNMP, which is implemented over the user datagram protocol (UDP) (Postel 1980; Bidgoli 2006). An SNMP agent must also implement SNMP and UDP protocols. Because UDP is a connectionless protocol, SNMP is itself a connectionless protocol. No outgoing connections are maintained between a management station and its agents. This design minimizes the complexity of the management agents.

Figure 3 also shows that SNMP supports five types of protocol data units (PDUs). The manager can issue three types of PDUs on behalf of a management application: *GetRequest*, *GetNextRequest*, and *SetRequest*. The first two are variations of the *get* function. All three messages are acknowledged by the agent in the form of a *GetResponse* message, which is passed up to the management application. Another message that the agent

generates is *trap*—an unsolicited message that is generated when an event that affects the normal operations of the MIB and the underlying managed resources occurs.

SNMP Protocol Specifications

The SNMP message package communicated between a management station and an agent consists of a version identifier indicating the version of the SNMP protocol, an SNMP community name to be used for this message package, and an SNMP PDU. The message structure is shown in Figure 4, and each field is explained in Table 2.

Structure of Management Information

Figure 3 shows the information exchange between a single manager and agent pair. In a real network environment, there are multiple managers and many agents. The foundation of a network management system is a management information base (MIB) containing a set of network objects

Table 2: SNMP Message Fields

Field	Functions
Version	SNMP version (RFC 1157 is version 1)
Community Name	A pairing of an SNMP agent with some arbitrary set of SNMP application entities (Community Name serves as the password to authenticate the SNMP message)
PDU Type	The PDU type for the five messages is application data type, which is defined in RFC 1157 as <i>GetRequest</i> (0), <i>GetNextRequest</i> (1), <i>SetRequest</i> (2), <i>GetResponse</i> (3), <i>trap</i> (4)
RequestID	Used to distinguish among outstanding requests by the unique ID
ErrorStatus	A non-zero <i>ErrorStatus</i> is used to indicate that an exception occurred while processing a request
ErrorIndex	Used to provide additional information on the error status
Variable-Bindings	A list of variable names and corresponding values
Enterprise	Type of object generating trap
AgentAddress	Address of object generating trap
GenericTrap	Generic trap type; values are <i>coldStart</i> (0), <i>warmStart</i> (1), <i>linkDown</i> (2), <i>linkUp</i> (3), <i>authenticationFailure</i> (4), <i>egpNeighborLoss</i> (5), <i>enterpriseSpecific</i> (6)
SpecificTrap	Specific trap code not covered by the <i>enterpriseSpecific</i> type
Timestamp	Time elapsed since last reinitialization

to be managed. Each managed resource is represented as an object. The MIB is in fact a database structure of such objects in the form of a tree (Stallings 1998). Each system in a network environment maintains an MIB that keeps the status of the resources to be managed at that system. The information can be used by the network management entity for resource monitoring and controlling. SMI defines the syntax and semantics used to describe the SNMP management information (McCloghrie 1999).

MIB Structure

For simplicity and extensibility, SMI avoids complex data types. Each type of object in an MIB has a name, syntax, and an encoding scheme. An object is uniquely identified by an OBJECT IDENTIFIER. The identifier is also used to identify the structure of object types. The term OBJECT DESCRIPTOR may also be used to refer to the object type (McCloghrie and Rose 1991). The syntax of an object type is defined using Abstract Syntax Notation One (ASN.1) (International Organization for Standardization 1987). Basic encoding rules (BER) have been adopted as the encoding scheme for data type transfer between network entities.

The set of defined objects has a tree structure. Beginning with the root of the object identifier tree, each object identifier component value identifies an arc in the tree. The root has three nodes: *itu* (0), *iso* (1), and *joint-iso-itu* (2). Some of the nodes in the SMI object tree, starting from the root, are shown in Figure 5. The identifier is constructed by the set of numbers, separated by a dot, that defines the path to the object from the root. Thus, the *internet* node, for example, has its OBJECT

IDENTIFIER value of 1.3.6.1. It can also be defined as follows:

```
internet OBJECT IDENTIFIER ::= { iso (1) org
(3) dod (6) 1 }.
```

Any object in the *internet* node will start with the prefix 1.3.6.1 or simply *internet*.

SMI defines four nodes under *internet*: *directory*, *mgmt*, *experimental*, and *private*. The *mgmt* subtree contains the definitions of MIBs that have been approved by the IAB. Two versions of the MIB with the same object identifier have been developed, *mib-1* and its extension *mib-2*. Additional objects can be defined in one of the following three mechanisms (Case et al. 1990; Stallings 1998):

1. The *mib-2* subtree can be expanded or replaced by a completely new revision.
2. An experimental MIB can be constructed for a particular application. Such objects may subsequently be moved to the *mgmt* subtree.
3. Private extensions can be added to the *Private* subtree.

Object Syntax. The syntax of an object type defines the abstract data structure corresponding to that object type. ASN.1 is used to define each individual object and the entire MIB structure. The definition of an object in SNMP contains the data type, its allowable forms and value ranges, and its relationship with other objects within the MIB.

Encoding. Objects in the MIB are encoded using the BER associated with ASN.1. Although it is not the most compact or efficient form of encoding, BER is a widely used, standardized encoding scheme. BER specifies a method for encoding values of each ASN.1 type as a string of octets for transmitting to another system.

Management Information Base

Two versions of MIBs have been defined: MIB-I and MIB-II. MIB-II is a superset of MIB-I, with some additional objects and groups. MIB-II contains only essential elements; none of the objects is optional. The objects are arranged into groups as shown in Table 3.

Security Weaknesses

The only security feature that SNMP offers is through the Community Name contained in the SNMP message as shown in Figure 4. Community Name serves as the password to authenticate the SNMP message. Without encryption, this feature essentially offers no security at all, since the Community Name can be readily eavesdropped as it passes from the managed systems to the management system. Furthermore, SNMP cannot authenticate the source of a management message. Therefore, it is possible for unauthorized users to exercise SNMP network management functions and to eavesdrop on management information as it passes from the managed systems to the management system. Because of these deficiencies, many SNMP implementations have chosen not to implement the Set command. This reduces their utility to that of a network monitor, and no network control applications can be supported.

Figure 5: Management Information Tree

Table 3: Objects Contained in MIB-II

Groups	Description
system	Contains system description and administrative information.
interfaces	Contains information about each of the interfaces from the system to a subnet.
at	Contains address translation table for Internet-to-subnet address mapping. This group is deprecated in MIB-II and is included solely for compatibility with MIB-I nodes.
ip	Contains information relevant to the implementation and operation of IP at a node.
icmp	Contains information relevant to the implementation and operation of ICMP at a node.
tcp	Contains information relevant to the implementation and operation of TCP at a node.
udp	Contains information relevant to the implementation and operation of UDP at a node.
egp	Contains information relevant to the implementation and operation of EGP at a node.
transmission	Contains information about the transmission schemes and access protocols at each system interface.
snmp	Contains information relevant to the implementation and operation of SNMP on this system.

SNMPv2

SNMP was originally developed as an interim management protocol, while CMIP over TCP/IP (CMOT), which essentially enables the OSI system management protocols to operate on top of the TCP protocol, was developed as the ultimate network management protocol. However, the latter goal never came about in reality. At the same time, SNMP has been incorporated widely, and enhancement is expected. SNMPv2 was developed when it was obvious that the OSI network management standards were not going to be widely adopted in the foreseeable future.

Major Changes in SNMPv2

The SNMPv2 system architecture is essentially the same as that of SNMP. The key enhancement in SNMPv2 can be summarized as follows:

- **Bulk data transfer capability:** The most noticeable change in SNMPv2 is the inclusion of two new PDUs. The first PDU is the `GetBulkRequest` PDU, which enables the manager to retrieve large blocks of data efficiently, and therefore speeds up the `GetNextRequest` process.
- **Manager-to-manager capability:** The second PDU is the `InformRequest` PDU, which enables one manager to send trap type of information to another, and thus makes network management systems interoperable.

- **Structure of management information:** The SMI defined in SNMP has been consolidated and rewritten.

SNMPv2 Protocol Specifications

To improve the efficiency and performance of message exchange between systems, the PDU data structure in SNMPv2 has been standardized to a common format for all messages, given in Figure 6. In the `GetBulkRequest` PDU, the `NonRepeaters` field indicates the number of non-repetitive field values requested and the `MaxRepetitions` field designates the maximum number of table rows requested.

SNMPv2 Structure of Management Information

The SMI for SNMPv2 is based on the SMI for SNMP. It is nearly a proper superset of the SNMP SMI. The SNMPv2 SMI is divided into three parts: module definitions, object definitions, and notification definitions.

Module definitions are used to describe information modules. An ASN.1 macro, `MODULE-IDENTITY`, is used to concisely convey the semantics of an information module. Object definitions are used to describe managed objects. `Object-Type` is used to concisely convey both syntax and semantics of a managed object. Notification definitions are used to describe unsolicited transmissions of management information. Notification in SNMPv2 is

PDU Type	RequestID	ErrorStatus	ErrorIndex	VariableBindings				
				Name 1	Value 1	...	Name N	Value N

(a) All but Bulk Type of PDUs

PDU Type	RequestID	NonRepeaters	MaxRepetitions	VariableBindings				
				Name 1	Value 1	...	Name N	Value N

(b) `GetBulkRequest` PDU**Figure 6:** SNMP entity

equivalent to trap in SNMP SMI. NOTIFICATION-TYPE conveys both syntax and semantics.

SNMPv2 Management Information Base

The SNMPv2 MIB defines objects that describe the behavior of an SNMPv2 entity. It consists of three groups:

- **System group:** An expansion of the original MIB-II system group. It includes a collection of objects that allow an SNMPv2 entity to act in an agent role to describe its dynamic configurable object resources.
- **SNMP group:** A refinement to the original MIB-II snmp group. It consists of objects that provide the basic instrumentation of the protocol activity.
- **MIB objects group:** A collection of objects that deal with SNMPv2Trap PDUs and that allow several cooperating SNMPv2 entities, each acting in a manager role, to coordinate their use of the SNMPv2 set operations.

Security Weaknesses

Similar to SNMP, SNMPv2 fails in providing any security services. The security of SNMPv2 remains the same as the SNMP. Therefore, it is still vulnerable to security attacks such as masquerade, information modification, and information disclosure.

SNMPv3

The security deficiency in SNMP and SNMPv2 significantly limits their utility. To remedy this problem, SNMPv3 was developed (Blumenthal and Wijnen 2002; Case et al. 2002; Harrington, Presuhn, and Wijnen 2002; Levi, Meyere, and Stewart 2002; Wijnen, Presuhn, and McCloaghrie 2002). The SNMPv3 configuration can be set remotely with secure communication links. SNMPv3 also provides a framework for all three versions of SNMP and future development in SNMP with minimum impact on existing operations.

SNMPv3 Architecture

An SNMP management network consists of a distributed, interacting collection of SNMP entities. Each entity consists of a collection of modules that interact with each

other to provide services. The architecture of an entity is defined as the elements of that entity and the names associated with them. There are three kinds of naming: naming of entities, naming of identities, and naming of management information.

SNMP Entities

The elements of the architecture associated with an SNMP entity, shown in Figure 7, consist of an SNMP engine, named `snmpEngineID`, and a set of applications that use the services provided by the SNMP engine. A brief description of each of the modules is given below.

- **Dispatcher:** Allows for concurrent support of multiple versions of SNMP messages in the SNMP engine. It performs three sets of functions. First, it sends and receives SNMP messages from the network. Second, it determines the version of the message and interacts with the corresponding message-processing model. Third, it provides an abstract interface to SNMP applications to deliver an incoming PDU to the local application, and to send a PDU from the local application to a remote entity.
- **Message-processing subsystem:** Responsible for preparing messages for sending, and extracting data from received messages.
- **Security subsystem:** Provides security services such as authentication and privacy of messages. It potentially contains multiple security models.
- **Access control subsystem:** Provides authorization services by means of one or more access control models.

SNMP Names. The names associated with the identities include `principal`, `securityName`, and a model-dependent security ID. A principal indicates to “whom” services are provided. A principal can be either a person or an application. A `securityName` is a human-readable string that represents a principal. A model-dependent security ID is the model-specific representation of a `securityName` within a particular security model.

A management entity can be responsible for more than one managed object. Each object is called a “context”

Figure 7: SNMPv2 PDU formats

Table 4: List of Primitives

Component	Primitive	Service Provided
Dispatcher	sendPdu	Sends an SNMP request or notification to another SNMP entity
	processPdu	Passes an incoming SNMP PDU to an application
	returnResponsePdu	Returns an SNMP response PDU to the PDU dispatcher
	processResponsePdu	Passes an incoming SNMP response PDU to an application
	registerContextEngineID	Registers responsibility for a specific contextEngineID, for specific pduTypes
	unregisterContextEngineID	Unregisters responsibility for a specific contextEngineID, for specific pduTypes
Message Process Subsystem	prepareOutgoingMessage	Prepares an outgoing SNMP request or notification message
	prepareResponseMessage	Prepares an outgoing SNMP response message
	prepareDataElements	Prepares the abstract data elements from an incoming SNMP message
Access Control Subsystem	isAccessAllowed	Checks whether access is allowed
Security Subsystem	generateRequestMsg	Generates a request or notification message
	processIncomingMsg	Processes an incoming message
	generateResponseMsg	Generates a response message
User-Based Security Model	authenticateOutgoingMsg	Authenticates an outgoing message
	authenticateIncomingMsg	Authenticates an incoming message
	encryptData	Encrypts data
	decryptData	Decrypts data

and has a contextEngineID and a contextName. A scopePDU is a block of data containing a contextEngineID, a contextName, and a PDU.

Abstract Service Interfaces. Abstract service interfaces describe the conceptual interfaces between the various subsystems within an SNMP entity and are defined by a set of primitives and the abstract data elements. A primitive specifies the function to be performed and the parameters to be used to pass data and control information. Table 4 lists the primitives that have been defined for the various subsystems.

SNMPv3 Applications

SNMPv3 formally defines five types of applications. These applications make use of the services provided by the SNMP engine. SNMPv3 defines the procedures followed by each type of application when generating PDUs for transmission or processing incoming PDUs. The procedures are defined in terms of interaction with the dispatcher by means of the dispatcher primitives.

Command Generator. The command generator application makes use of the sendPdu and processResponsePdu dispatcher primitive to generate GetRequest, GetNextRequest, GetBulk, and SetRequest messages. It also processes the response to the command sent. The

sendPdu provides the dispatcher with information about the intended destination, security parameters, and the actual PDU to be sent. The dispatcher then invokes the message-processing model, which in turn invokes the security model, to prepare the message. The dispatcher delivers each incoming response PDU to the correct command generator application, using the processResponsePdu primitive.

Command Responder. A command responder application makes use of four dispatcher primitives (registerContextEngineID, unregisterContextEngineID, processPdu, and returnResponsePdu) and one access control subsystem primitive (isAccessAllowed) to receive and process SNMP Get and Set requests. It also sends response messages. The dispatcher delivers each incoming request PDU to the correct command responder application, using the processPDU primitive. The command generator uses returnResponsePdu to deliver the message back to the dispatcher.

Notification Originators. A notification-originator application follows the same general procedures used for a command-generator application to generate either a trap or an Inform. If an Inform PDU is to be sent, both the sendPDU and processResponse primitives are used. If a trap PDU is to be sent, only the sendPDU primitive is used.

Notification Receiver. A notification receiver application follows a subset of the general procedures as for a command responder application to receive SNMP notification messages. Both types of PDUs are received by means of a `processPdu` primitive. For an `Inform` PDU, a `returnResponsePdu` primitive is used to respond.

Proxy Forwarder. A proxy-forwarder application makes use of dispatcher primitives to forward SNMP messages. The proxy-forwarder application handles four types of messages: messages containing PDU types generated by a command-generator application, messages containing PDU types generated by a command-responder application, messages containing PDU types generated by a notification-originator application, and messages containing a report indicator.

SNMPv3 Management Information Base

Three separate MIB modules have been defined by Levi et al. (2002) to support SNMPv3 applications: the management target MIB, the notification MIB, and the proxy MIB.

The `SNMP-TARGET-MIB` module contains objects for defining management targets. It consists of two tables. The first table, the `snmpTargetAddrTable`, contains information about transport domains and addresses. The second table, the `snmpTargetParamsTable`, contains information about SNMP version and security information to be used when sending messages to particular transport domains and addresses.

The `SNMP-NOTIFICATION-MIB` module contains objects for remote configuration of the parameters used by an SNMP entity for the generation of notifications. It consists of three tables. The first table, the `snmpNotifyTable`, selects one or more entries in `snmpTargetAddrTable` to be used for the generation of notifications. The second table, the `snmpNotifyFilterProfileTable`, sparsely augments the `snmpTargetParamsTable` so as to associate a set of filters with a particular management target. The third table, the `snmpNotifyFilterTable`, defines filters used to limit the number of notifications generated for a particular management target.

The `SNMP-PROXY-MIB` contains objects for the remote configuration of the parameters used by an SNMP entity for proxy-forwarding operations. It contains a single table, `snmpProxyTable`, which is used to define the translations between management targets for forwarding messages.

SNMPv3 Message Format

Each SNMPv3 message includes four data groups: `msgVersion`, `msgGlobalData`, `msgSecurityParameters`, and `msgPDU`, as shown in Figure 8.

The `msgVersion` field is set to `snmpv3` (3) and identifies the message as an SNMP version 3 Message. The `msgGlobalData` field contains the header information. The `msgSecurityParameters` field is used exclusively by the security model. The contents and format of the data are defined by the security model. The `msgData` is the scoped PDU field containing information to identify an administratively unique context and a PDU.

Security Enhancement

One of the main objectives in developing SNMPv3 is the addition of security services for network management. SNMPv3 is intended to address four types of security threats: modification of information, masquerade, disclosure, and message-stream modification. The first two are identified as principal threats, while the last two are identified as secondary threats. A user-based security model (USM) is proposed in SNMPv3. This model reflects the traditional concept of a user identified by a `userName` (Blumenthal and Wijnen 2002).

User-Based Security Model (USM)

The USM encompasses three different security modules: the authentication module, the timeliness module, and the privacy module.

In order to protect against message replay, delay, and redirection, when two management entities communicate, one of the SNMP engines is designated to be the authoritative SNMP engine. Particularly, when an SNMP message contains a payload that expects a response, then the receiver of such messages is authoritative. When an SNMP message contains a payload that does not expect a response, then the sender of such a message is authoritative.

The message process model invokes the USM in the security subsystem. Based on the security level set in the message, the USM in turn invokes the authentication modules, privacy modules, and timeliness module. The USM allows for different protocols to be used instead of, or concurrent with, the protocols described by Blumenthal

Figure 8: SNMPv3 message format

and Wijnen (2002) and Wijnen, Presuhn, and McCloghrie (2002).

Authentication. USM uses one of two alternative authentication protocols to achieve data integrity and data origin authentication: HMAC-MD5-96 and HMAC-SHA-96. HMAC uses a secure hash function and a secret key to produce a message authentication code (Stallings 1998; Krawczyk, Bellare, and Canetti 1997). In this case, the secret key is the localized user's private authentication key `authKey`. The value of `authKey` is not accessible via SNMP. For HMAC-MD5-96, MD5 is used as the underlying hash function. The `authKey` is 16 octets in length. The algorithm produces a 128-bit output, which is truncated to 12 octets (96 bits). For HMAC-SHA-96, the underlying hash function is SHA-1. The `authKey` is 20 octets in length. The algorithm produces a 20-octet output, which is again truncated to 12 octets.

Encryption. USM uses a cipher block chaining data encryption standard (CBC-DES) symmetric encryption protocol to protect against disclosure of the message payload (Stallings 1998; Krawczyk et al. 1997). A 16-octet `privKey` is provided as the input to the encryption protocol. The first 8 octets (64 bits) of this `privKey` are used as a DES key. Since DES uses only 56 bits, the least significant bit in each octet is disregarded. For CBC mode, a 64-bit initialization vector (IV) is required. The last 8 octets of the `privKey` contain a value that is used to generate this IV.

In order to ensure that the IVs for two different packets encrypted by the same key are not identical, an 8-octet string called "salt" is XOR-ed with the pre-IV to obtain the IV.

View-Based Access Control Model (VACM). The access control subsystem of an SNMP engine has the responsibility

for checking whether a specific type of access (read, write, notify) to a particular object (instance) is allowed.

Access control occurs in an SNMP entity when processing SNMP retrieval or modification request messages from an SNMP entity and when an SNMP notification message is generated.

The VACM defines a set of services that an application can use for checking access rights. It is the responsibility of the application to make the proper service calls for access checking.

Remote Network Monitoring (RMON)

Remote network monitoring devices, often called "monitors" or "probes," are instruments that exist for the purpose of managing a network. The RMON can produce summary information of the managed objects, including error statistics, performance statistics, and traffic statistics. Based on the statistics information, the status of the managed objects can be observed and analyzed.

RMON1 Groups

The RMON1 specification is primarily a definition of an MIB, defined by Waldbusser (1993, 2000). RMON1 delivers management information in nine groups of monitoring elements; each provides specific sets of data to meet common network-monitoring requirements. Some RMON1 groups require the support of other RMON1 groups to function properly. Table 5 summarizes the nine monitoring groups specified in Waldbusser (1997).

RMON2

RMON2 as defined by Waldbusser (1997) enables network statistics and analysis to be provided from the network layer up to the application layer. The most visible and most beneficial capability in RMON2 is monitoring

Table 5: RMON1 MIBs

RMON Group	Functions
Statistics	Contains statistics measured by the probe for each monitored interface on this device.
History	Records periodic statistical samples from a network and stores them for later retrieval.
Alarm	Takes statistical samples periodically from variables in the probe and compares them with previously configured thresholds. If the monitored variable crosses a threshold, an event is generated.
Host	Contains statistics associated with each host discovered on the network.
HostTopN	Prepares statistics about the top <i>N</i> hosts on a subnetwork based on the available parameters.
Matrix	Stores statistics for conversations between sets of two addresses. As the device detects a new conversation, it creates a new entry in its table.
Filters	Enables packets to be matched by a filter equation. These matched packets form a data stream that may be captured or may generate events.
Packet capture	Enables packets to be captured after they flow through a channel.
Events	Controls the generation and notification of events from a device.
Token ring extensions	Contains four groups to define some additional monitoring functions specified for token ring. They are the ring station group, the ring station order group, the ring station configuration group, and the source routing statistics group.

Table 6: RMON2 MIBs

RMON2 MIB Group	Functions
Protocol directory	Presents an inventory of protocol types capable of monitoring.
Protocol distribution	Collects the relative amounts of octets and packets.
Address mapping	Provides address translation between MAC addresses and network addresses on the interface.
Network-layer host	Provides network host traffic statistics.
Network-layer matrix	Provides traffic analysis between each pair of network hosts.
Application-layer host	Reports on protocol usage at the network layer or higher.
Application-layer matrix	Provides protocol traffic analysis between pairs of network hosts.
User history collection	Provides user-specified history collection on alarm and configuration history.
Probe configuration	Controls the configuration of probe parameters.
RMON conformance	Describes the conformance requirements to RMON2 MIB.

above the MAC layer, which supports protocol distribution and provides a view of the whole network rather than a single local area network (LAN) segment. RMON2 also enables host traffic for particular applications to be recorded. The managed objects in RMON2 are arranged into groups, as shown in Table 6.

Mobility Management in Wireless Networks

The major feature of wireless communication is that it supports user mobility. Handoff management and location management are two key components in mobility management of wireless networks (Mark and Zhuang 2003).

Handoff Management. Wireless networks have the flexibility to support user roaming. To facilitate user roaming, there must be an effective and efficient handoff mechanism so that the mobile's connection can be transferred from one access point to another access point with continued service.

An effective handoff scheme should have the following features: (1) fast and lossless, (2) minimal number of control signals, (3) scalable with network size, and (4) capable of recovering from link failures.

Location Management. For identification purposes, each wireless subscriber must register with its home network. The subscriber's identity is a permanent address that resides in the database of a location register, called the subscriber's home location register (HLR). When the subscriber moves away from his/her home network, the new address the mobile enters is a visitor network. It must update its registration with the home location register through its visitor location register (VLR) in order to facilitate message delivery to the mobile in its new location. The procedure of maintaining an association between the mobile and its HLR when it is away from its home network is referred to as location management.

Location management is achieved mainly through location update and paging. The location update procedure allows the system to keep location knowledge in order

to find the user for incoming calls. The paging process achieved by the system consists of sending paging messages in all cells in which the mobile terminal could be located.

NETWORK MANAGEMENT TOOLS AND SYSTEMS

The tremendous growth in scale and diversity of computer networks has made network management a complex and challenging task for network administrators. To manage computer networks tangibly and efficiently, specific management tools and systems must be used to seamlessly monitor the network activities and to preemptively determine and control the network behaviors.

The catalog of network management tools and systems is extensive, and it is far beyond the scope of this chapter. Network management tools are usually based on particular network management protocols. Most tools use open protocols; however, some network management tools are based on vendor-specific proprietary protocols. The network management capabilities provided with the tools are usually based on the functionality supported by the network management protocols.

In this section, we will briefly describe network management tools in several categories, including network monitors, network scanners, and packet filters, along with two network management systems.

Network Monitors

One of the fundamental responsibilities of a network administrator is network monitoring. Network monitors are responsible for collecting and analyzing network traffic. A good system should be able to generate log files and performance charts that detail the system capabilities and responses. With these data, the network configuration can be optimized and better prepared for faults. Some network monitors are designed with SNMP management capability to offer full view of the fundamental network issues. Based on the observation of network monitors,

network configuration can be optimized, and the administrators can be better prepared for faults. To minimize the network down time, effective network monitoring will alert the presence of a network anomaly immediately.

Numerous network monitoring tools are available today. Based on the functionalities, network monitoring tools may be further divided into the following categories:

- **Network and system monitoring** can enhance commercial network and system performance. Representative examples of network and system monitoring include ActiveXperts Network Monitor (www.activexperts.com/activmonitor), AdventNet OpManager (<http://manageengine.adventnet.com/products/opmanager>), GFI Network Server Monitor (www.gfi.com/nsm), and ipMonitor (www.ipmonitor.com/default.aspx).
- **Network traffic monitoring** can monitor traffic flows through and between critical network devices as well as collect utilization statistics. Examples of network traffic monitoring tools include Colasoft EtherLook (www.etherlook.com) and TracePlus Ethernet (www.sstinc.com/ethernet.html).
- **Protocol analyzing and packet capturing** provide packet capture, network sniffers, performance monitors and so on. Distinct Network Monitor (www.distinct.com), WildPackets' Etherpeek (www.wildpackets.com/products/etherpeek/overview), and Network Probe (www.objectplanet.com/probe) are some examples in this category.
- **Security monitoring** provides security monitoring of workstations and servers. Activeworx Security Center (www.activeworx.com/products/asc/index.html) and NetOp Desktop Firewall (www.netop.com/netop-14.htm) are two examples in this category.

Network Scanners

Network security vulnerabilities are being detected on a daily basis. A network scanner is one of the key elements of network security. It checks network system, operating system, and applications running on the network to identify vulnerabilities and possible security flaws that could expose the network to security compromise. To protect online assets and eliminate the risk to the business, some network scanners can also automate vulnerability assessment. Some representative network security scanners include Internet Scanner, Nessus Network Vulnerability Scanner, SAINT Vulnerability Scanner, Retina Network Security Scanner, NetIQ Vulnerability Manager, and GFI LANguard Network Security Scanner.

Packet Filters

Packet filters control access of data packets to a network by scanning the contents of the packet headers. A packet filter determines whether a packet should be allowed to go through a given point based on certain access control policies.

Packet filtering is most commonly used as the first line of defense against attacks from machines outside the network. It has become a common and inexpensive mechanism for security protection. However, packet filtering

does not guarantee the security of the network and internal data.

Dynamic packet filtering, also referred to as stateful inspection, is a firewall architecture that works at the network layer. Stateful inspection tracks each connection traversing all interfaces of the firewall and makes sure they are valid. A stateful firewall may examine the contents of the packet up through the application layer in order to get more information about the packet other than its source and destination. A stateful inspection firewall also monitors the state of the connection and compiles the information in a state table. As a result, filtering decisions are based not only on administrator-defined rules but also on context that has been established by prior packets passed through the firewall.

Simple packet filters are implemented in most routers and operating systems. Some well-known packet filters include netfilter (Linux) (www.netfilter.org), PF (OpenBSD) (www.openbsd.org/faq/pf), ipfilter (Unix) (<http://coombs.anu.edu.au/~avalon>), and SmartSniff (Windows) (www.nirsoft.net/utils/smsniff.html).

Network Management Systems

A network management system (NMS) is an automated system tool that helps networking personnel perform their functions efficiently. Many network management systems are available today. In this section, three network management systems will be briefly introduced.

- **HP OpenView** (<http://h20229.www2.hp.com>) is HP's network management platform. It is most commonly described as a suite of software applications that allow large-scale system and network management of an organization's IT assets. It includes hundreds of optional modules from HP as well as thousands of third parties that connect within the well-defined framework and communicate with one another.
- **Network Node Manager (NNM)** is the network system built on the HP OpenView platform. The HP OpenView platform provides the common management services that are accessed through standard application programming interfaces (APIs). NNM is also used in its own right to manage networks, possibly in conjunction with other products, such as Cisco CiscoWorks.
- **IBM Tivoli** (<http://222-306.ibm.com/software/tivoli>) is a systems management platform from IBM. It is a CORBA-based architecture that allows the platform to manage large numbers of remote locations or devices. Tivoli includes a huge list of software tools in providing management functions. These tools can be largely divided into four major categories, including business service management, security management, storage management, and system management.

POLICY-BASED NETWORK MANAGEMENT—SOLUTIONS FOR THE NEXT GENERATION

Policy-based network management (PBNM) (Strassner 2004) is a way to manage the configuration and behavior

Figure 9: The basic model of policy-based management

of one or more entities based on business needs and policies. PBNM systems enable business rules and procedures to be translated into policies that configure and control the network and its services. PBNM can also be defined as a condition-action response mechanism. The general form is:

```
ON <event>
IF <conditions>
THEN <actions>
```

PBNM enables an automatic response to conditions in the network according to predefined policies. By automating the network management, the entire network can be managed as an entity itself. The essence of PBNM is portrayed in Figure 9.

Policy-based network management (PBNM) will redefine the way networks are being managed. Policy management is necessary to administer network QoS (quality of service), security, and resources throughout the enterprise.

What Is a Policy?

Policy is typically defined as a set of operating rules that manage and control access to network resources. It allows a network to be managed through a descriptive language. Policy can be represented at different levels, ranging from business goals to device-specific configuration parameters.

Policy management is the use of operating rules to accomplish decisions. It forms a bridge between the service-level agreement (SLA) and the network entities. Business goals and policies can be defined as a separate business management layer on top of the service management layer that provides services such as QoS, as shown in Figure 10 (Erfani et al. 1999).

Figure 10: Network management—layered view

With the growth in scale and complexity of computer networks, QoS and security are becoming very challenging management issues. PBNM is emerging as a promising solution in simplifying the management of QoS and security.

Benefits of PBNM

The appealing part of PBNM is that through abstractions, the network management QoS and security mechanisms can be simplified so that the majority of network management tasks are simple in nature. PBNM also enables system behavior to be changed without modifying the implementation. More specifically, the benefit of PBNM can be summarized as follows (Strassner 2004; Hewlett-Packard 1999):

- **Optimizes network resource intelligently:** The automation of management tasks intelligently optimizes both the use of network infrastructure and the network policies. PBNM reduces the need for adding bandwidth to congested links.
- **Simplifies network and service management:** PBNM users are no longer required to be specialists in order to perform network management functions. Another aspect is that changes in business policies do not necessarily require any low-layer development, which makes management updating painless.
- **Manages complex traffic and services intelligently:** PBNM can manage applications with competing demand for shared resources using the predicated traffic information. Unauthorized and unwanted applications can be controlled or eliminated, while mission-critical applications can be assigned with special priority.
- **Performs time-critical functions efficiently:** PBNM can simplify and better implement the time-critical functions, such as changing device configurations within a specific time window and performing scheduled provisioning functions.
- **Provides better security:** PBNM can help categorize traffic into expected and unexpected types and assign rules to deal with each type. PBNM can also be used to determine whether a particular user can access a resource or not.

Architecture of a PBNM System

The general architecture for a policy-management system is shown in Figure 11. This architecture contains four major components (Hewlett-Packard 1999; Westerinen et al. 2001):

- **Policy Management Console:** The user interface to construct policies, deploy policies, and monitor the status of policy-managed environment.
- **Policy Repository:** A database that stores the policy rules, their conditions and actions, and related policy data. It can also be defined as a model abstraction representing an administratively defined, logical container for reusable policy elements.

Figure 11: A logic architecture for PBNM

- **Policy Decision Point (PDP):** A logical process that makes decisions based on the policy rules and the conditions under which the policy rules are applied.
- **Policy Enforcement Point (PEP):** A logical entity that executes policy decisions and/or makes a configuration change.
- **Policy Communication Protocols:** Needed for data exchange between entities in the policy management system. The common object policy service protocol (COPS) is often mentioned to support the communication between the PDP and the PEP.

CONCLUSION

In this chapter, after a brief introduction of the network management system, the evolution of the two most widely used network management standards, SNMP and RMON, is reviewed along with the rapid development in computer and communication networks. Network management tools and systems, which have become an indispensable element in network management, are then briefly introduced. As a promising solution for the next generation of network management, the architecture of PBNM is also discussed. The popularity of SNMP and RMON is due largely to their simplicity in architecture and implementation; however, the simplicity comes with limitations as well. The versatile expertise required for the administrators and the reality that even a slight change in business policy may require complex development at lower layers, prevent these standards from further development. To overcome these disadvantages, PBNM is proposed to ensure efficient network management and smooth network services upgrade. Although PBNM is not yet fully mature, its promising features make it very appealing and convincing for a rosy future.

GLOSSARY

Account Management: One of the five OSI systems management functional areas. Consists of facilities that enable cost allocation based on the use of network resources.

Common Management Information Protocol (CMIP): An object-oriented OSI standard management protocol.

Configuration Management: One of the five OSI systems management functional areas. Consists of facilities that set and change the configuration of networks and network components.

Fault Management: One of the five OSI systems management functional areas. Consists of facilities that detect, isolate, and correct the abnormal operation of the OSI environment.

HMAC Protocols: Message authentication protocols used for the authentication scheme in security management. It is based on hashing algorithms to derive the message access code (MAC). Two common algorithms used in SNMP security management are HMAC-MD5-96 and HMAC-SHA-96.

Managed Object: A network device that can be managed remotely by a network management system.

Management Information Base (MIB): An abstract definition of the management information available through a management interface in a system.

Network Management System (NMS): The platform that houses the network manager module. It monitors and controls the network components from a centralized operation.

Network Monitoring: Network monitoring describes the use of a system that constantly monitors a computer network for slow or failing systems and that notifies the network administrator of outages via e-mail, pager, or other alarms.

Network Scanner: Network scanner describes the systems used to check the network system, the operating system, and applications running on the network to identify vulnerabilities and possible security flaws that could expose the network to security compromise.

Packet Filter: A packet filter determines whether a packet is allowed to go through a given point based on certain access control policies.

Performance Management: One of the five OSI systems management functional areas. Consists of facilities that evaluate the behavior of managed objects and the performance of network activities.

Policy-Based Network Management (PBNM): Manages the configuration and behavior of networks based on business needs and policies.

Remote Network Monitoring (RMON): Remotely monitoring the network with a probe.

Security Management: One of the five OSI systems management functional areas. Consists of facilities that provide security services essential to operate OSI network management correctly and to protect managed objects.

Simple Network Management Protocol (SNMP): An application layer protocol that facilitates the exchange of management information between network devices.

Structure of Management Information (SMI): Defines managed objects and their characteristics, as well as the relationship between the objects.

Trap: An alarm or an event generated by a management agent and sent in an unsolicited manner to a network management system.

User-Based Access Control Model (UACM): The access control scheme defined in SNMPv3. It is more secure and flexible than the simple access policy defined in SNMP.

INTRODUCTION

E-mail and IM systems are the two main categories of software described in this chapter, and emphasis is placed on security issues and solutions. After a brief introduction to electronic mail and instant messaging, a more detailed look at each system is presented. In today's world of increasing cybercrime, security in e-mail and IM environments is an important concern. Security issues and possible solutions are examined in depth for both e-mail and IM. Following this discussion, e-mail and IM usage policies are suggested. The conclusion is followed by a glossary of key terms and a list of references.

ELECTRONIC MAIL

Electronic mail is ubiquitous in communication today. Before the usefulness of e-mail was perceived, the Internet was widely used initially for military and academic purposes. The growth in popularity of the Internet was due, in part, to e-mail. Compared to other modes of communication, such as postal mail, e-mail is cheaper, faster, and more convenient. The ability to forward communications to many people and to address more than one recipient, as well as the asynchronous nature of the communication, makes e-mail popular. The advent of mailing lists and address books added convenience and ease of use, leading to an upsurge in the use of e-mail.

Definition of E-Mail

Per the popular usage of the term, e-mail can be defined as mail sent via electronic means. According to Lombardi (2003), e-mail messages use standard conventions for addressing and delivering content across the public Internet. An e-mail has two mandatory parts: a header and a message. Other components, including attachments, are optional. In the beginning of e-mail history, all e-mails were in text format. As e-mail systems evolved, formatting styles other than plain text began to be used. The e-mail header contains information on where the e-mail originated,

the route it has traveled, and to whom it is addressed. Although most e-mail users may dismiss the header as irrelevant to their communication, technical staff need to know the source, destination, and route of the e-mail in case of problems.

Brief History of E-Mail

Ray Tomlinson adapted an existing internal e-mail program to the ARPAnet file transfer technology and sent the first e-mail message from one computer to another in 1971 (Griffiths 2002). After the first message, "Testing 1-2-3," was successfully sent and received by two different computers, Tomlinson sent a message to all ARPAnet users and gave them instructions for sending and receiving electronic mail. The convention username@hostname, which is the basis for e-mail today, dates from this time.

Initially, e-mail was cumbersome and not user-friendly. However, most of the modern e-mail features were implemented within a year of the first e-mail transmission (Griffiths 2002). The ability to delete, forward, and save messages, together with a standard protocol to transfer messages between programs, was established by 1972. Thus, e-mail evolved along with the network now known as the Internet. In 1977, a standard specification of e-mail was published in a document called RFC 733, which was revised in 1982 to describe domain name syntax explicitly for the first time (Crocker 2003).

Eric Allman developed the sendmail program in the 1980s, which was derived from e-mail relaying on the UNIX operating system at the University of California at Berkeley. In 1988, Vinton Cerf sent the first commercial e-mail by connecting MCI Mail to the NSFnet (National Science Foundation network). This event marked a milestone in the history of e-mail because it paved the way for the network service providers America Online and Delphi to connect their proprietary e-mail systems to the Internet. The exponential growth in e-mail use can be traced to this moment when the benefits of e-mail were globally recognized.

Advantages and Features of E-Mail

Some people consider one of the advantages of e-mail to be its informal style of communication. Although people expect typed letters to be formal and perfect, no such expectations exist for e-mail. E-mail became more popular because of its relatively low cost, high reliability, and almost instantaneous delivery as compared with regular mail (Living Internet 2003). E-mail provides a high level of informality, a sense of community and sharing, wide tolerance of spelling and typographical errors, and brevity of expression. It has been theorized that the style of e-mail communication was a factor in its early and continued success. Also, unlike the telephone, e-mail does not demand an immediate response (Griffiths 2002).

Scientists and researchers working in the ARPAnet (precursor to the Internet) community started to recognize the immense promise of e-mail to change the way people communicate in all sectors of society, including the academic, business, and cultural sectors (Myer and Dodds 1976). Productivity gains were realized by businesses through the use of e-mail. Today, e-mail has become indispensable in academic, governmental, and business organizations around the world because of ease of use, convenience, low cost, asynchronous nature, range of features, and communication efficiency.

Current E-mail Systems

An e-mail system has three components: the transport agent and the delivery agent on the server, and the user agent or client (Preetham 2002). Popular graphical-user-interface (GUI)-based e-mail clients such as Eudora, Google mail, Mozilla Thunderbird, Microsoft's Outlook and Outlook Express, and Pegasus incorporate features such as e-mail forwarding, read receipts, e-mail filtering, and spam blocking. Web-based clients such as Hotmail and Yahoo are also popularly used. While Web-based clients do not require software downloads onto people's personal computers, non-Web-based GUI e-mail clients such as Eudora require downloads.

Besides the GUI-based e-mail clients mentioned previously, popular text-based e-mail clients include elm and pine. An e-mail client can use either the post office protocol (POP) or the Internet mail access protocol (IMAP). POP copies e-mails from the server to the computer on which the client resides, whereas IMAP works by copying e-mail headers to the client computer—actual e-mail messages are not copied unless selected (Nevis 2004).

On Outlook for Microsoft Exchange server, messaging application programming interface (MAPI) can be used for retrieving e-mail. For sending e-mail, simple mail transfer protocol (SMTP) is the de facto standard for transmission, whereas multipurpose Internet mail extensions (MIME) is another popular protocol available for e-mail clients (Wikipedia 2006). For server software, Exchange and sendmail protocols are popularly used. On Linux, qmail is a widely used protocol on the e-mail server. Howstuffworks.com has simple diagrams that provide a clearer understanding of the e-mail transfer process and SMTP protocol.

MIME is a protocol that provides the ability to transmit nontext data such as graphics and audio through e-mail.

Text-based encoding is used so that the nontext data can be transported through text-based e-mail gateways. The specifications for the MIME protocol are documented in RFC 1521 and RFC 1522; these documents also specify the standard representation for "complex" message bodies (ELook.org 2006). A complex message body is the body of an e-mail message that does not follow a human-readable ASCII format of default e-mail messages. Digitally signed e-mail messages and file attachments sent with textual e-mail are some examples of complex message bodies.

E-mail addresses can be grouped together into mailing lists. A manager program automates the tedious maintenance of the list by adding, modifying, and deleting users and their e-mail addresses. Most corporations use standard naming procedures to make e-mail administration and management easier (Tittel 2002). Popular e-mail server software can be categorized into proprietary intranet solutions such as Microsoft's Exchange program and the Internet-based sendmail program. Web-based e-mail software abounds, and providers make these clients available to users for free. For instance, Yahoo! and Hotmail provide free e-mail quotas of 250 MB to each user. Google mail (Gmail) provides more than 2 GB to each user.

Disadvantages and Vulnerabilities of E-mail

Although more detail can be found in "E-Mail Threats and Vulnerabilities," this chapter provides a high-level perspective on e-mail vulnerabilities and disadvantages. The very advantages of e-mail can be construed as disadvantages under certain circumstances. The asynchronous nature of e-mail results in disadvantages such as the lack of face-to-face presence that is vital to effective communication. Terse messages can mislead the recipient, especially if previous threads to an e-mail conversation are not attached. E-mail is hampered by the lack of visual cues that are sometimes necessary to understand what the sender really means (Counseling 2003). Some people find it ineffective to communicate solely via e-mail because its asynchronous nature means there is an absence of immediate, real-time responses.

Today's e-mail systems are more vulnerable to attacks than earlier ones because of the many additions made to the basic model. Advanced formatting such as hypertext markup language (HTML) and the sending of attachments via e-mail contribute to the propagation of viruses and spam. It is also easy to impersonate others via e-mail. Recipients may be led to believe that the e-mail is from someone they know, but the sender's name and e-mail address could have been impersonated by a crook.

Standard procedures and default configurations are vulnerabilities in e-mail systems. For example, standard naming procedures that ease e-mail management are predictable and thus exploited by hackers. Malicious users hide their identities by using anonymous addresses of publicly available Web-based e-mail providers such as GMail, Yahoo!, and Hotmail (Kruse and Heiser 2002). Source addresses can be spoofed. Even if the sender's Internet protocol (IP) address is logged, it may not be of much use because the hacker may be using a computer in a public place such as a library or an airport.

Other threats to e-mail include interception and modification of messages and distortion of message headers and content to hide the source and route of traversal (Pfleeger 1997). Sophisticated protection systems exist today to resolve these threats. E-mail filters work in conjunction with firewalls and intrusion-protection systems to create layers of blocking measures for potential malicious software. Sender identity and e-mail privacy are resolved by security measures such as public/private key encryption and digital signatures. "Cryptography," has detailed information about encryption.

Spam, or unsolicited e-mail (often undesirable), is an ever-growing problem and has surpassed legitimate e-mail in volume. Because spam constitutes over 60 percent of all email in 2006 as of the date of this writing (Barracuda Networks 2006), spam filtering for e-mail is a must, especially in the enterprise, if employee productivity and network bandwidth are to be protected against the adverse effects of spam. Commercial implementations of spam filters include SpamAssassin, Spamihilator, SpamBouncer, SPAMfighter, Spam Bully, and Barracuda Spam Firewall. Spam filters use many techniques for preventing false positives, that is, legitimate e-mails flagged as spam. Bayesian learning techniques, bouncing spam back to the sender, Turing test filters, IP address black listing, and e-mail stamps have been used successfully against spam.

The Bayesian spam filter has an initial time period to "learn" user preferences about spam e-mails and legitimate e-mails (Graham 2002). Spam filters also exist that can send a fake bounce message to the spammer after simulating an e-mail delivery failure. The Turing test filter requests a human response for a potential spam e-mail before placing it in the inbox (Knight 2003). With e-mail stamps, a charge can be imposed before allowing the spam messages to go through to the sender. Other spam blocking techniques are surveyed in a Barracuda Networks white paper (Barracuda Networks 2006).

Malicious people such as virus writers usually exploit the features of e-mails to spread their destructive payload. An e-mail virus usually spreads from computer to computer by automatically mailing itself to all the e-mail addresses in the victim's address book. The Melissa virus of 1999 spread through Microsoft Word documents attached via e-mails (Brain 2004). Social engineering attacks are also common via e-mail. The "I Love You" virus that spread in 2000 was an example.

The virus writers exploited the trust that prompted readers to open the e-mail message because the subject line contained the phrase "I Love You." Thus, e-mail readers inadvertently spread the malicious virus. Until this virus was released, most e-mail was trusted, especially ones that came from a trusted source such as a coworker or spouse (Miller 2000). Some people also thought that it may have been a joke because e-mail was popularly used for distributing jokes. The Love bug virus, as it came to be known, caused damage that was expensive to repair; both in terms of money and lost time/productivity and in terms of eroding trust in e-mailed messages.

Another example is the recent spate of "phishing" attacks that exploit e-mail's ubiquity in order to harvest confidential data of unsuspecting users who click on an apparently genuine URL in an e-mail purportedly from

a legitimate authority (FTC 2003). Phishing and phishing attacks are on the rise today, and continue to be one of the areas of concern in e-mail security.

A key concern is the confidentiality of e-mail communication. Because an e-mail can pass through many servers from source to destination, it can be stored and/or retrieved at any point along its route. Network administrators and high-level managers have the right to read all e-mail passing through their networks. Employees may not be aware that e-mail communication is neither private nor confidential. Law enforcement officials can confiscate e-mail on servers and backups for investigative purposes. Later in this chapter, e-mail use policies are described that elaborate on the procedures necessary to alert employees about e-mail communication.

Safeguards for E-mail: Filters and Usage Policies

Several vulnerabilities posed by e-mail communication make the presence of monitoring systems inevitable today, especially in large corporate environments. The process of monitoring e-mail and taking certain actions based on predefined criteria is referred to as e-mail filtering. E-mail that is monitored can be incoming or outgoing; messages need to match predefined criteria, which can be changed at any time. E-mail filters can help sort, forward, and delete incoming and outgoing e-mail. On an organization-wide level, e-mail filters might be installed:

- to disinfect viruses from attachments
- to block unsolicited e-mail (spam)
- to block confidential information from going outside the company,
- to block incoming and outgoing offensive content
- to prevent unauthorized usage of corporate e-mail systems (Bhagyavati and Yang 2004).

E-mail filtering software is currently available from Lyris, ePrism, MailMate, SurfControl, and SpamAssassin. Although e-mail filters are necessary to monitor spam and offensive e-mail, their implementation can have unintended consequences, such as blocking legitimate e-mail or blacklisting naïve users accused of sending unsolicited e-mail. Cross-compatibility issues among e-mail filters and antivirus software may cause unintentional propagation of viruses.

Monitoring and matching measures add extra time to the delivery of e-mail. These security measures also inhibit the free flow of communication that is vital for research and creativity in organizations. The unintended effect of these filters could cause a shift away from e-mail by annoyed employees.

Because e-mail is frequently used to communicate with colleagues, peers, and superiors, a lack of usage guidelines can lead to confusion over appropriate content and message form. Lack of an e-mail use policy can have serious consequences in cases of inappropriate communication. If corporations do not have policies on e-mail use, employees can misuse corporate-owned e-mail systems

without fear of consequences. In creating a written e-mail policy, all “do’s and don’ts” need to be included.

Employees must also be trained to understand fully why policies are important. Implementation of the rules can be monitored by management tools (EmailReplies.com 2001). Professionalism, efficiency, and liability protection are the primary reasons for an organization to implement etiquette rules and train its employees on them. Sending e-mails in uppercase letters, attaching unnecessary files, making grammatical and spelling errors, and requesting read receipts frequently are all etiquette policy violations.

Consequences for policy violations vary widely by state and by the type of organization. For example, the consequences for violations in a not-for-profit organization run by volunteers may be different from the consequences faced by employees in traditional businesses. Also, the penalties may range from reprimand to termination, depending on the severity of the offense, the scope and definition of the policy, and the enforcement mandated within the company. Sample policy guidelines are as follows (SANS 2006):

1. Office e-mail may not be used for commercial purposes or for personal gain. Distribution of spam or flame e-mails is not tolerated from office computers.
2. Confidential and sensitive information should not be sent via e-mail, unless it is encrypted. Because e-mail communication is free and open, anyone can obtain such sensitive information. Encryption makes the message impossible to read if the deciphering key is not available.
3. E-mail communications on office systems will be monitored for appropriateness of use.
4. Due diligence needs to be practiced while communicating via e-mail; although an e-mail has been deleted by the recipient, it can be retrieved and used against the sender or the workplace.
5. Inappropriate and offensive material, which is not suitable for distribution otherwise, should not be transmitted through e-mail. For example, off-color remarks, racist comments, pornographic material, and other unsuitable material should not be sent through office e-mail.
6. E-mail communication needs to be concise and work-related. Incidental personal use is permitted only if it does not interfere with office operations.
7. E-mail recipients should be limited only to those with a need to know the contents of the communication. Forwarding and copying to everyone in the workplace should be avoided.
8. If copyrighted information or trademarks are sent via e-mail, the recipient must have a need to know the information and should be able to securely receive the e-mail.
9. Use of office e-mail implies that the sender acts as an agent on behalf of the employer. Appropriateness of tone, style, content, and form of e-mail will ensure that high standards of work and professionalism are maintained.

INSTANT MESSAGING

Instant messaging systems extended the chat service available on time-shared computers to the Internet. IM client programs on users’ computers connect to specialized servers that monitor all IM users and maintain buddy lists for each user. America Online (AOL) popularized the IM service with its AIM (AOL Instant Messenger), which is freely available for download from its Web site. IM can be thought of as an online, real-time version of e-mail (Day, Rosenberg, and Sugano 2000). In today’s fast-paced corporate environment, employees do not wish to wait for recipients to check e-mails and then respond; instead, real-time and interactive responses are expected. The use of instant messaging grew exponentially in the late 1990s (Ralston, Reilly, and Hemmendinger 2003).

Definition of IM

Instant messaging is a type of real-time communication via the Internet that enables a user to create a private chat room with another user (Webopedia 2006). Whereas e-mail can be compared to postal mail, IM can be compared to a telephone conversation. However, a telephone conversation is voice-based, whereas an IM conversation is largely text-based. The IM system allows a user to create and maintain a buddy list of other users; the system alerts the user when any of the buddies is online. The user is then free to initiate an IM session with the buddy. For IM to work, both users must download and install an IM client, and both users must be logged on to the Internet at the same time.

Brief History of IM

Internet relay chat (IRC) was a messaging program invented in 1988 that was IM-like in its functionality. More about IRC can be found in “Internet Relay Chat (IRC).” In November 1996, four Israeli programmers introduced ICQ (“I seek you”), which was a free instant-messaging utility that anyone could use by downloading a client capable of real-time communication (Tyson 2004). Because of the sense of community it created, online services were popular even before the growth in popularity of the Internet.

America Online, long considered the pioneer of the online community, had provided chat rooms for its users before it introduced AIM, its version of IM services. Although AIM uses proprietary protocols to enable users to IM each other, non-AOL users can talk to AOL users; this explains the dominance of AIM in the IM marketplace. The development of standards and protocol specifications by the Internet Engineering Task Force popularized the use of IM and pushed the technology to the mainstream (Day, Rosenberg, and Sugano 2000).

The future of instant messaging appears promising because of heightened interest among the business and common user community. The fact that 85 percent of all businesses today acknowledge the use of IM within their organizations is testimony to the growing popularity of instant messaging solutions. Since IM software is going to be downloaded and used by employees,

companies want to control the deployment process and manage security as well.

Advantages and Features of IM

IM appears attractive to people on projects that require more real-time interaction than e-mail can provide. Employees on team projects need not check their e-mails frequently; instant messaging provides interactive and real-time contact among them (Deutschle 2003). Synergies of work and a boost in productivity are usually reported when an organization deploys IM. Communicating in real-time streamlines interactions and saves time and money. In addition, free IM client software implies reduced licensing and contractual fees for communication. Employee frustration can also be minimized because IM facilitates immediate access to colleagues.

Long-distance telephone bills can be reduced by using IM. Spam can be reduced because the sender and recipient communicate in real time. IM provides an opportunity for employees to hold conferences and chats (IM-Age 2006). It also speeds up internal and external communications and provides network-independent access to communication. However, several corporations are hesitant to deploy IM because of inadequate security. Corporate policy sometimes may not deter employees from using public-domain IM clients without IT approval. This activity may result in inadvertent disclosure of confidential corporate information.

Current IM Systems

Although AIM and ICQ are the leaders in the IM race, other popular IM systems include Microsoft's MSN Messenger, the open-source multiprotocol GAIM, Google Talk, and Yahoo! Messenger (YM). Utilities such as Odigo and Omni allow the user to combine multiple IM services in one application (Tyson 2004). MSN Messenger and YM allow users to talk via IM just like via the telephone, provided both parties have the necessary equipment, such as microphone and speakers, to access the voice feature.

Today's IM programs also incorporate file-sharing and file-transfer capabilities. Mobile devices such as handhelds, tablet personal computers (PCs), and Internet-enabled cellular telephones are capable of communicating via instant messaging systems. There are two main categories of second-generation secure IM products: (a) IM clients with security features built in and (b) IM management software that can monitor any of the products currently popular among users. Zone Labs' product "Integrity IM Security," FaceTime Communications' "IM Auditor," and IM-Age's "Policy Manager" management solution belong to the latter category.

These products do more than secure IM; they handle policy management and provide centralized security (Zone Labs 2006; FaceTime Communications, 2006; IM-Age 2006). For example, Zone Labs' IM Policy Manager authenticates internal IM users, blocks file transfers, and monitors employee communications. Niksun's "NetDetector" can detect anomalies, reconstruct IM sessions, and archive IM for long-term storage (Niksun 2002). Microsoft Communicator is another IM system that allows corporate

entities to secure their IM environments. It also allows IM communication with other popular IM systems. The Internet has diagrammatic representations of instant messaging concepts—the diagram that appears on Learnthenet.com is one such example.

Disadvantages and Vulnerabilities of IM

Basic IM is not a secure way to communicate. The content of instant messages and information about user (network) connections are maintained on servers controlled by the IM provider. Although most of the large IM providers offer encryption, user logs have been captured by malicious hackers in the past (Deutschle 2003). The perception among employers is that IM is uncontrollable; therefore, the whole network becomes compromised. Buffer overflow vulnerabilities in IM clients can lead to attacks that result in denial of service and/or execution of arbitrary code. Open ports can be found by hackers via file transfer on IM. Malware can be spread using file sharing and transfer.

Proprietary client software, word limits on messages and sessions, potential for employee misuse, and security concerns have managed to restrain the popularity of IM in the business environment. Because IM does not leave an audit trail, the corporation cannot monitor the conversation. Proprietary consumer products such as MSN Messenger and ICQ are unsuited for enterprises because they allow unencrypted data and bypass the virus protection at the corporate network's gateway servers. The file-transfer capability of IM is especially insecure in this regard. Service providers such as AOL and Sprint have developed separate enterprise versions of their proprietary IM solutions that address corporate security concerns.

Safeguards for IM, and Usage Policies

Buffer overflow vulnerabilities found in popular instant messaging applications such as Yahoo! Messenger and AIM serve as a reminder that hackers can take control over other machines for coordinated attacks at a later time (Weber 2004). Because consumer-level IM programs do not use encryption, these programs cannot be used in corporate environments without modification. IM also allows hackers to become aware of user presence—that is, whether the user is online or offline. Social engineering, which can lead to identity theft, is also common because of poor authentication practices. Security concerns are, therefore, paramount in presence-aware IM environments.

According to security experts, insecure IM is the new target for hackers who seek to steal sensitive corporate information. Firewalls and intrusion-detection systems are not useful unless they are integrated with IM-security software (Gaudin 2002). Employees sending noncorporate information on IM can waste network bandwidth. IM can also cause easy distraction and loss in productivity. Offensive jokes propagated through IM can lead to harassment suits. Because of legal and ethical ramifications of IM use, an enterprise needs to structure IM use policies

and train employees before deploying the IM solution. Sample policies include the following:

1. Confidential and sensitive information should not be sent via IM unless it is encrypted. Because IM communication is insecure, anyone can obtain such sensitive information.
2. IM communications on office systems will be monitored for appropriateness of use.
3. Inappropriate and offensive material, which is not suitable for distribution otherwise, should not be transmitted through IM. For example, off-color remarks, racist comments, pornographic material, and other unsuitable material should not be sent through office IM.
4. IM communication needs to be concise and work-related. Incidental personal use is permitted only if it does not interfere with office operations.
5. Use of office IM implies that the sender acts as an agent on behalf of the employer. Appropriateness of tone, style, content, and form of IM will ensure that high standards of work and professionalism are maintained.

SECURITY IN E-MAIL AND IM ENVIRONMENTS

Security is a significant area of concern in an e-mail environment because e-mail is the most crucial form of communication medium available on the Internet (Preetham 2002). To ensure the integrity of e-mail communication, various measures have been implemented. Not caring about e-mail security could result in the sender's identity being compromised, the recipient's identity being compromised, or leakage of sensitive information. If the transfer agent and client of an e-mail system can be secured on the network, the service provider can secure the delivery agent. Encryption software can ensure security on the communication channel. Security measures can also guard against address spoofing and anonymous e-mail.

Features of secure environments include confidentiality of message content, authentication of sender and recipient, and assurance of message integrity (Kurose and Ross 2003). Public key cryptography (more detail in "Cryptography"), symmetric key cryptography, digital signatures, message digests, message integrity checks, trusted key distribution, and certificate validating authority are essential to secure all e-mail communication within the environment. Because IM clients are used on mobile handheld devices such as PDAs and cellular telephones in addition to desktop and laptop computers, the security risks are higher because of the inherent vulnerabilities of wireless transmission. The lack of secure environments exacts a productivity and monetary toll.

E-Mail Security: Issues and Practices

User awareness and training are probably the most important tools to secure e-mail. Deleting unsolicited messages, not opening suspicious attachments, encrypting sensitive information sent via e-mail, and using spam filters are effective practices for ensuring the security of e-mail communications (Weber 2004). Corporate policies

will not amount to much if users are not trained on implementing the policies and made aware of the consequences of violations. Security-savvy users can thwart social engineering attacks that try to obtain log-in and password information from them.

Other security measures to follow in an e-mail environment include using proxy servers to forward e-mail to the clients and using an updated antivirus program to check all incoming and outgoing e-mail. Modern antivirus programs are capable of heuristic analysis of viruses by safely monitoring their behavior under controlled conditions (Sandhu 2002). Installation of antivirus software must be augmented by prompt updating of virus definitions and patterns; otherwise, the antivirus software will not be effective against newly generated viruses and other malware, such as Trojan horses and worms, which may infect application software.

IM Security: Issues and Practices

Patch management and avoidance of spying software are the first steps in securing IM systems. Antivirus software and intrusion-detection and intrusion-protection programs will limit the security vulnerabilities of IM systems. However, corporate entities can ensure IM security by not allowing their employees to use public-domain IM systems such as AIM and YM. Proprietary solutions combined with end-to-end security provide a better defense than freeware.

Solutions from FaceTime Communications, IMlogic, Akonix Systems, and MessageLabs provide software and hardware to manage IM systems in enterprises (Hoover 2006). These providers claim that viruses sent through IM will be detected, unintentional transmission of sensitive information will be controlled, and the IM security solution will be integrated with preexisting antispam, content scanning, and encryption programs (FaceTime Communications 2006). For example, if unauthorized IM or P2P (peer-to-peer) connections are detected, they are blocked and logged.

Realizing that the corporate environment was not ready to accept insecure IM systems, service providers such as AOL and Sprint developed enterprise versions of their IM clients, specifically tightening or adding security features. AOL's Enterprise AIM service allows system administrators to manage IM use from behind the corporate firewall (Deutschle 2003). Although the security features come at a steeper price than the virtually free consumer versions, companies are expected to invest in IM's long-term advantages. Other security-hardened IM products include IBM's Lotus Sametime and Bantu's Presence Platform. An encrypted version of Sametime is used by the U.S. military and some academic institutions.

Security providers such as Zone Labs have developed management platforms for securing IM in the enterprise and ensuring privacy for IM communications (Zone Labs 2006). This program is independent of the IM client and can execute equally well on AIM, MSN Messenger, and YM. According to Zone Labs, this product is compatible with its firewall product, so both can be integrated to form an end-to-end solution. Featuring IM encryption, spam blocking, password protection, and security logging,

this product is geared toward the security-conscious corporate marketplace. Other vendors such as IM-Age and Niksun have also developed secure IM products or IM management software.

CONCLUSION

E-mail has become one of the primary means of communication for people today (Tyson 2004). E-mail clients that allow users to send, receive, and manage their messages evolved from different formats and storage systems. E-mail clients differ in how they track e-mail and where they store archived data (Nelson et al. 2004). Hence, no single security solution can be provided for their varying vulnerabilities and differing reactions to threats.

Because of its ubiquitous nature, several viruses now use e-mail as a distribution and reproduction mechanism because of its potential for rapid, worldwide spread. Security concerns must be weighed critically before sending confidential data through the system. Behavior-based monitoring of virus activity, integrity checks, detection of changes in content and sources and destinations of e-mail, signature-based searches, and heuristic, real-time scanning can mitigate security risks (Slade 2004).

The Gartner Group, in October 2001, opined that IM, like e-mail, could cause a company to operate as a real-time enterprise if it is properly managed and integrated into the underlying infrastructure. Today, IM is being used by 85 percent of all businesses (Hoover 2006). Although IM is perceived to be ephemeral, every message can be stored by the service provider or the organization. These archives can be monitored and even used in evidence. Hence, it is prudent to exercise care in sending e-mail and IM messages.

GLOSSARY

Antivirus Software: Software programs that detect and eliminate viruses, worms, Trojan horses, and other malware.

Authentication: The process of ensuring that the individual is who she says she is.

Confidentiality: The act of keeping sensitive information secretive.

Demilitarized Zone (DMZ): A computer or a subnetwork that is installed between a trusted internal network and an untrusted external network.

Digital Certificate: An attachment to an e-mail used for security purposes such as verifying the sender's identity to the receiver.

E-Mail: An asynchronous communication tool analogous to postal mail; it is used to transmit messages via the Internet.

Encryption: The process of translating data into a secret code; it is the most effective way to achieve data confidentiality.

Filter: Software or hardware that monitors and blocks incoming and outgoing e-mail traffic.

Firewall: Hardware and/or software designed to prevent unauthorized access to or from a private network.

Instant Messaging: An interactive, synchronous tool for engaging in real-time communication via the Internet.

Intrusion-Detection System: A system that inspects all inbound and outbound network activity to identify suspicious patterns that may indicate an attack.

Malware and Spyware: Malicious software designed to damage a system. Spyware is software that gathers user information through the Internet connection without his or her knowledge, usually for advertising purposes.

Message Integrity: This refers to the validity of e-mail transmissions.

Nonrepudiation: When the recipient of a communication has the ability to ensure that the sender is unable to deny the sending of the message or the authenticity of its signature on the communication.

Patch Management: Process of updating and managing patches and temporary fixes on a frequent and regular basis so as to remain current on the latest updates of the software.

Proxy Server: A server that sits between a client application and another server; it intercepts all requests to the actual server. Proxy servers improve efficiency and filter harmful traffic.

Spam: Electronic junk mail or unsolicited, targeted advertisement via e-mail.

Use Policies: Policies regarding employee use of organization-owned computers for e-mail and IM.

Virtual Private Networks: A private network developed by using public wires to connect nodes. A virtual private network uses encryption and other security mechanisms, thus ensuring that corporate data are safe traveling on the public Internet.

Viruses, Worms, and Trojan Horses: Malicious software that infect a host computer, then replicate and spread to other computers via the network to cause more damage.

Vulnerabilities and Threat Assessment: A process of proactively identifying vulnerabilities (weaknesses) in computers of a network to determine if and where a system can be exploited and/or threatened (attacked).

INTRODUCTION

Application service providers (ASPs) have become acceptable external sources of software services for many organizations. In the basic ASP model, a vendor hosts an application required by a client and delivers the application services over a network. In one variation of the basic ASP model, application services are not customized. In another variation of this model, as in managed service provisioning (MSP), more customized services are provided. In fact, a variant of the ASP model in which software services were obtained from a vendor was in existence during the early days of computing, and this was called time-sharing (Braunstein 1999). However, with advances in networking and data communications technologies, ASP has become more widely used as a viable alternative to in-house IT departments and other forms of outsourcing (Dibbern et al. 2004) for obtaining IT applications (Currie 2004). According to a recent Gartner research study “almost one third of US companies currently use application service providers and another 22 percent plan to do so in the next two years” (Betts 2005). This trend in the use of ASPs follows a previous period of decline from 2001 to 2004 that occurred with the bursting of the “dot com bubble.”

Traditionally, a company purchasing application software from a vendor installed the software in the company's own systems, either on a network or in a single system, and maintained the software and user data. This traditional approach can become too costly for some companies, or a company may not possess enough technical skills and suitable technologies to implement and manage the purchased software. In such cases, companies may instead decide to contract with an ASP. In contrast to the traditional approach, a company seeking services from an ASP will obtain the services of the application from the vendor's servers, which hosts the applications. In this ASP arrangement, the customer company pays the vendor a periodic fee for the use of the software. Such an arrangement can benefit companies when they do not want to spend money to purchase software outright or to set up the infrastructure for hosting the software. Although cost is a main advantage for a company seeking ASP services, risks such as data security and lack of control over the application still exist when using an ASP. The objective of this chapter is

to discuss the ASP model, the types and characteristics of ASP arrangements, and the benefits and risks of ASPs.

In general, many digital or electronic business services offered by vendors are described using terms ending with “SP.” In their attempts to use a generic term, some people have coined the term ‘xSP’ to refer to the different service providers (Means 2004; Dickerson 2002). Because of the wide spectrum of services falling under this category of xSPs, it is necessary to define the scope of the topic of this chapter. Obtaining IT services related to networking from external sources can be referred to as “netsourcing” (Kern, Lacity, and Willcocks 2002, Netsourcing). The netsourcing spectrum includes application service providers (ASPs), business service providers (BSPs), commerce service providers (CSPs), ExSourcers, full-service providers (FSPs), managed service providers (MSPs), and storage service providers (SSPs). Although some explanations in this chapter are applicable to more than one type of service providers, our intent here is to cover only the ASP area.

Network configurations and capabilities are critical for the successful use of any ASP, and specific network configuration requirements and capacities will vary, depending on the client's demands. The network-configuration-related technical capabilities are only one type of factor essential for success. A client's demand for ASP depends on many nontechnical determinants. The nontechnical determinants for using an ASP in an organization can be classified as economic, strategic, and knowledge-related. Before explaining the organizational criteria for choosing an ASP and the associated applications, we need to discuss the ASP model, the network hardware and software making the ASPs possible, and ASP configurations. Finally, the feasibility assessment criteria for choosing an ASP are also discussed.

ASP BUSINESS MODELS

This section examines the important factors in ASP business models—technical infrastructure, vendor-customer relationship management, support staff, and contract. As mentioned in the introduction, current studies indicate increased use of ASPs in the future (Betts 2005). The expected increase in demand is due to the potential benefits

of the ASP model. The ASP sourcing option is capable of delivering best-of-breed business applications in a scalable and flexible manner. Typically, an organization can obtain these services in exchange for a periodic fee (e.g., either a monthly or an annual fee) based on the number of transactions generated and/or the number of users at a customer's site. In addition, some vendors provide free online application services such as Yahoo's calendar, e-mail, and file-management applications in My Yahoo.

The types of ASPs have grown since the early days, when vendors primarily rented software to their clients (Tebboune 2003). One of the early definitions of *application service provider* was "a form of selective sourcing where a third-party organization rents generally available packaged software and related services" (Bennett and Timbrell 2000). Today, the application services have evolved to encompass different types of services. ASPs are no longer limited solely to renting software packages. The vendors can host and manage applications developed by customers, or the vendors can be other software developers who provide their services to customers.

Many popular software products of independent software vendors (ISVs) can be rented from the ASPs. Rented software products range from organizationwide enterprise resource planning (ERP) applications such as packages from JD Edwards, Oracle, Peoplesoft, and SAP to individual-level applications such as personal productivity software from Google, Microsoft, and Netscape. At a functional level, ASPs provide e-commerce and e-business software for specific business functions such as supplier relationship management (from CommerceOne), customer relationship management, and sales force automation (from salesforce.com and SSA Global). Because of the availability of many different ASP options, taxonomies of ASPs can help clarify the world of ASPs. Before examining the taxonomies of ASPs, an examination of generic models will be helpful in understanding the specific available service options. Several elements are common to all of the different ASP arrangements. The fundamental elements are the clients or customers who need application software services and the service providers or vendors who possess the resources to provide these services.

Vendor-Client Relationship

Some of the essential elements of an ASP arrangement are: (1) delivery of the services, (2) integration of the ASP service with the rest of the client organization as needed, and (3) management and operations necessary for providing/obtaining services and enabling the services appropriately. Delivery of the services requires infrastructure providing connectivity between the clients and the vendor. Integration with the rest of the organizational activities requires software compatibility, suitable technical infrastructure, as well as business processes that can be integrated with ASP services. Delivery, integration, management and operations, and enablement require technology and human resources.

The ownership of resources is an important aspect of the vendor-client relationship that must be examined when obtaining software services from vendors. Typically, the software package and the data reside at the vendor

location, and the client personnel access the software from their own location. This spatial separation of vendor and client necessitates some infrastructure to be at the vendor and some infrastructure to be at the client. Based on these infrastructure requirements, most of the resources in these ASP arrangements are owned by the service providers. The vendor must have: (1) the software package, (2) infrastructure to host and deliver the services to the client location, (3) the resources for storage and management of the data related to the application, and (4) the resources necessary to manage the application and networks. At the client end, the ownership will often be limited to the workstations and client network connectivity.

The essential components of an ASP arrangement are depicted in Figure 1. The model shows the relationships between the ASP and the clients in terms of the nontechnical factors. In the figure, a vendor supports many clients through a network. The network connecting the vendor and clients can be the Internet or a proprietary wide area network (WAN); therefore, the network is shown as a cloud shape in Figure 1. The network configurations will be discussed more specifically in the next section. At the vendor site, software, hardware, and networking capabilities enable providing the services to the clients. In addition, adequate managerial and technical support must be available at the vendor site. Clients need connectivity within their organization to distribute the application services as necessary and workstations to interface with the vendor systems. Moreover, proper vendor relationship management efforts at the client side can ensure success of the sourcing arrangement. Finally, both client and vendor behavior occur within the terms, conditions, and service levels stipulated in the contracts defining the ASP services to be delivered. Contract and service levels are discussed later in this section, and the contract is only one means to ensure receiving an efficient and effective service from the vendor.

Hosting applications and providing services to customers must be done efficiently and effectively. Typically, this means that the services should be available on demand. The application runs on the vendor server, and it is possible that the server performance is poor. Because of the server's poor performance, the application may not respond when a user needs to use it. For example, a user at the client end may want to make a customer service decision that requires information generated by the vendor application. If the application does not respond on time the user will not be able to make a timely decision. Such slow response may cause customer dissatisfaction. In addition to the server, other components such as communication media, switches, and protocols can also impact performance and availability. Because of the service-on-demand objectives and the likelihood of experiencing unacceptable performance, mechanisms to ensure quality of service (QoS) meeting the demands on time must be implemented. Providing quality and service levels requires enabling managerial processes and structures.

Managerial processes and structures for management of the applications and the networks are critical mechanisms for the success of ASPs. One managerial activity essential for the success of an ASP is proper IT operations management. The management must ensure that

Figure 1: One-to-many ASP model

applications are running on the server when needed, the data residing at the ASP are backed up and kept securely, the servers are running uninterrupted without glitches, recovery from failures is done appropriately, and the networks are performing efficiently. It is the responsibility of the vendor to put these managerial structures in place, including adequate support staff to ensure that the services are delivered at the anticipated levels. Therefore, the ASP support staff must reside mostly at the vendor site rather than at the customer site. On the client side, a client needs a management structure in place to manage its relationship with the vendor. The complexity of this structure may depend on the extent of services obtained from external vendors. As an example, if it is a single vendor and a single application, the existing internal IT managers at the client may be able to effectively oversee the relationship with the vendor. On the other hand, if a company obtains many services from several different ASPs, it may be more effective to set up a formal management structure dedicated to managing all the relationships with the ASPs.

The vendor provides services to the clients within a contractual framework, incorporating the essential aspects of service provisioning, terms, and conditions in the contract. The contract should be specific and adequately detailed to provide the framework for providing the services at the acceptable levels and to establish an appropriate

fee structure (Oakes 2005; Weblaw 2003). Obviously, the contract must stipulate the basics, such as fees to be paid by the client, the extent of service to be provided by the service provider, and the acceptable levels of service. The extent of service refers to the number of users given access to the application and the number of workstations that will have connectivity to the application's server. Service levels must specify the performance levels such as the availability of the application, down time, and acceptable time for fixing a problem so that the application will be up and running before the acceptable time elapses.

A service-level agreement (SLA) provides a framework for the delivery of services and for the measurement of service quality. More specifically, an SLA specifies services to be delivered, service availability, performance measures, arrangement for managing problems and performance, and the costs, as well as the penalties if the vendor does not meet stipulated service levels. The penalties may not be directly stated but often will be in the form of reduced payment for partial fulfillment of services. Oakes (2005) suggests that at least the following items must be addressed by an SLA.

- Customer and vendor responsibilities
- Problem definition, prioritization, and problem tracking

- Roles and responsibilities of each entity, such as network management and client network personnel
- Detailed information regarding help-desk services
- Problem escalation procedures—that is, procedures describing how and when problem solving moves to the next level and what the next level is if a problem is not solved by the first level of technicians or personnel
- Performance monitoring and reporting
- Quality-of-service guarantee
- Dispute-resolution procedures
- Security issues—such as data security and network security
- Termination of service provisions

In addition to these stipulations, other clauses must be included in an ASP contract to mitigate the risks. Details of the risks are discussed later in this chapter. For example, the contract should include clauses indicating the actions that must be taken if the vendor or the client needs to withdraw from the contract prematurely. Another important contractual specification relates to penalties if the service levels or the contractual terms are not met by either party (i.e., vendor or customer). As an illustration, consider a vendor who made the application available only 80 percent of the time and the client company has agreed to 95 percent as an acceptable availability. The contract should stipulate the amount of penalty for the reduction of availability by 15 percent experienced by the client.

In general, based on the number of vendors and clients in an ASP vendor-client relationship, there are four possible ASP arrangements: many-to-one, many-to-many, one-to-many, and one-to-one. Although many different vendors in a consortium can provide services to one client or an alliance of clients (forming many-to-one and many-to-many relationships), one-to-one and one-to-many occur more commonly. This section describes the latter two. Often, a single vendor serves many client companies with the same application. This scenario establishes one-to-many client-vendor relationships. The one-to-many relationship when providing the software implies that there will be no or minimal customization of the software.

Taxonomies of ASPs

Figure 1 demonstrates the basic one-to-many ASP model. In reality, this model is too simplistic to characterize the many complexities in the ASP industry. One way to understand the complexities in ASP business models is to classify all the different ASP arrangements that occur in practice (Currie, Desai, and Khan 2004; Kern, Lacity, and Willcocks 2002, Application service provision). According to a taxonomy based on the type of services provided (Currie et al. 2004), four types of ASPs are identifiable: (1) enterprise, (2) vertical, (3) horizontal, and (4) pure-play. In addition to these four types of ASPs providing their services directly to the clients, there are many ASP enablers who provide hardware, telecommunications, or Internet connectivity.

Enterprise ASPs provide enterprise-wide applications software, which usually can be used in different divisions or groups in an organization. An example of applications

offered by an enterprise ASP is enterprise resource planning (ERP) software (such as Peoplesoft, JD Edwards), which integrates manufacturing, accounting, and other functional areas. The enterprise ASPs do not restrict their solutions to the Internet only and thus could be offered over other WANs as well. Pure-play ASPs, on the other hand, offer Web-enabled applications only (e.g., salesforce.com offering sales force management and customer relationship management [CRM] software only over the Internet).

A vertical ASP offers services to a specific industrial sector. Two examples of vertical ASPs are: Trizetto (an ASP offering services to the health sector) and Constructware (an ASP offering application services to the construction industry). Other business sectors in which vertical ASPs offer services are engineering, hospitality management, insurance, finance, legal, transportation, retail, and wholesale (ASP directory 2000; Tebboune 2003). Another way to look at the different service providers is to examine the entities required for obtaining application services such as software, network infrastructure, and management (Ekanayake, Currie, and Seltsikas 2003). In contrast to the vertical ASPs that specialize in a specific sector, horizontal ASPs can cater to different industries using a specific application. For example, salesforce.com is a horizontal ASP offering sales force application software services across different vertical markets. From the vendor side, there are disadvantages and advantages to the different types of ASPs because of the limitation in their markets and the ability to specialize. A vertical ASP has a market limited to their specialization, but on the other hand, they will have better expertise in a given industry. A vendor providing services to the construction industry has a client base limited to construction companies, but the vendor will have the expertise to provide the necessary services to the construction industry.

Different players are necessary to implement ASPs successfully, and it is possible to classify these vendors taxonomically. According to this taxonomy, there are: ASP resellers, ASP developers, ASP aggregators, hosting services, and managed service providers (Currie et al. 2004). ASP resellers offer software from other developers for rent over networks. Applications for ERP and CRM are typical packages offered by ASP resellers. Some ASPs have developed their own software and deliver them over the networks. For example, Employeease (Employeease 2006) rents their human resource information/management software over the Internet. ASP aggregators integrate and market packages developed by ASP developers and ISVs. For example, Jamcracker (Jamcracker 2006) offers solutions for service management, user management, and access management solutions to service providers. A hosting service hosts a client's application. A hosting service is responsible for providing the server to host the application.

In a one-to-many ASP business model customers are offered software that is not customized—all the customers use the same software. However, businesses often have their own idiosyncratic needs that must be met. In such cases, ASP vendors have to customize the applications according to the customers' requirements. Such customization makes the one-to-many ASP model inapplicable. Instead, with customization we can see a model that can

be called a one-to-one model, although it may not be a strictly one-to-one model in which each customer is served with a specific application (or an application with specific features). Figure 2 shows the modified ASP model to represent the one-to-one vendor-client relationship. Figure 2 is somewhat similar to Figure 1. The main difference is that the vendor now provides customized versions of applications X and Y to the clients. A variant of an ASP model is emerging, called “managed service providers” (MSPs), and according to this model the vendor provides more-customized services (Collett 2005). In addition to the application services, MSP provides other services such as network management. For this reason, MSP is not explicitly addressed in this chapter.

Note that taxonomies are based on certain criteria used for classifications, and those discussed above are not the only possible classifications. For example, according to Webopedia (Webopedia 2006), ASPnews.com classifies ASPs as: enterprise ASPs, local/regional ASPs, specialist ASPs, vertical ASPs, and volume business ASPs.

NETWORK COMPONENTS AND ASP CONFIGURATIONS

Successful ASPs depend on cost-effective communications and reliable services. We now examine the network components of such a communications system. Before discussing the network requirements of an ASP, let us look at a typical scenario of an ASP user. The ASP user signs on to a workstation or to a local computer that is connected to a network. Once the local computer is running, the user selects the remote application program to run or signs on to the service provider before selecting the remote program. Typically, the actual location of the application is transparent to the user. The server at the vendor end runs the application and sends responses to the user's requests back to the user interface at the local computer. The user at the local computer uses her keyboard and mouse to interact with the program. Depending on the type of application, the user may save data on the local computer or at the vendor's site. Applications that work with large volumes

Figure 2: One-to-one ASP model with customized applications

of data are often stored at the vendor's site. However, this arrangement depends on the user needs and the resources of the user. In both cases, some data will be stored at the vendor location.

An ASP configuration implementing the described scenario is a typical client-server configuration, in which certain hardware and software needs to be at both the vendor and customer sites. The customer uses an interface, which can be either a common Internet browser or an application-specific interface depending on the software. At the customer site, the client systems run their own operating systems on suitable hardware. The operating system can be A/UX, Linux, Mac OS X, or Microsoft Windows (XP, 2000, etc.) or other Unix versions that run on a compatible platform (i.e., Apple Macintosh or PC). Similarly, the customer's hardware platform can be any type, conditional on compatibility between the operating system and the hardware. The users' client systems at the customer end must be compatible with the ASP's systems so they can be connected to the vendor's server through a communications network. Often, the customer systems are on a local area network (LAN). Some companies may also have a wide area network (WAN) that connects their systems and networks. Figure 3 shows the client systems at the customer end with a user's hardware platform connected to a customer's network infrastructure, in which the network infrastructure can be a LAN or a WAN. Figure 3 is given here to complete the description; more on LANs and WANs can be found in separate chapters in this handbook. The components at the client site are shown as a stack, in which client workstation hardware and software are connected to the network infrastructure. At the client site, a user interface to the application appears, and the operating system, which ultimately runs on the hardware platform, supports the interface.

The vendor's application runs on a server providing accessibility, efficiency, and security. Although the server's operating system need not be the same type as that of the users, the vendor's server must be running an operating system capable of providing reliable, efficient, effective, secure, and on-demand access to the application. As mentioned earlier, the server needs to run an application that properly enables access from many different types of systems at the workstations or client systems that the users are using. Such accessibility from different client

Figure 3: Customer/user end—client

Figure 4: Vendor end—server

systems requires proper application server software. A comparison of application server software is available at TheServerSide.com (Serverside 2006), and some vendors have their own solutions for application servicing (Citrix 2006). The application server software runs on the server operating system (Fitzgerald and Dennis 2005; PC World 2006) and the server-hosting hardware platform runs the operating system. The server operating system provides a platform for applications to run on, and the operating system must possess the features to enable access requests coming from many different types of clients. Definitely, the server operating system must possess multi-user capabilities as well as features providing security and stability. The server hardware platform is connected to the local network infrastructure at the vendor, which in turn must be linked to a network connecting to the customer's networks. The vendors' system can be represented as a stack, shown in Figure 4. Similar to Figure 3, Figure 4 is given here to complete the description. The essential feature of the system in the application server is the facility for serving remote users in different system environments. The server must meet the essential performance levels in terms of response time, throughput, availability, reliability, and in some cases, the ability to handle time-dependent/critical user interactions. Moreover, the server system must provide facilities for user management, including keeping user accounts and data and security management.

As mentioned earlier, for customers to use the applications at the vendor site, connectivity must exist between the vendor and customer networks. The necessary connectivity can be achieved through the Internet. Theoretically, any WAN that provides communications facilities between the customers and vendors can be used, as shown in Figure 5. Secure communications between the customers and vendors are necessary.

In these situations, the vendor and the customer can connect through secure networks such as virtual private networks (VPNs). In using a VPN, the Internet can provide the underlying physical communications capabilities while the VPN offers the secure connectivity required. The Internet often provides a more cost-effective way to connect vendor and customer networks. Figure 6 shows the connection between several customers and a vendor network through the Internet and through a VPN. In Figure 6, Customer X is using a more secure VPN to

Figure 5: Vendor-customers networking through WAN

Figure 6: Vendor-customers networking

connect to the ASP while the other customers communicate through the Internet.

The Internet, instead of another type of proprietary or customized WAN, offers both advantages and disadvantages. The Internet offers an inexpensive method of communications between the vendor and clients, but the communications are more vulnerable to external threats. Moreover, both the vendor and the client have to depend on other organizations for availability of the network (e.g., sometimes the Internet may go down and an Internet service provider (ISP) may be slow to respond). Another problem with the current Internet is the unpredictable performance. At times, because of heavy use and the type of data being transferred, the user might experience slow response time while using an application via the Internet. In such situations, time-critical applications might not perform as desired. Performance degradation caused by the Internet may be beyond the control of the ASP.

A proprietary or customized WAN is more costly, and is maintained by either the vendor or the client. With direct involvement of the vendor, the client, or both in maintaining the WAN, both parties will have more control over the network, allowing for more secure networks versus using the Internet. By considering these benefits and problems of the network configurations, one can evaluate whether to use a specific delivery network. The other organizational and business issues that need to be considered prior to making ASP decisions will be discussed later. The following section describes the ASP configuration in general and associates it with the different types of vendors, for each type of activity.

ASP MODEL ELEMENTS AND RELATED VENDORS

ASPs are not always vendors just offering their applications to customers over networks. As described in the

previous section, the ASPs can serve as many different types of ASPs in the vendor market. We now examine the overall ASP infrastructure in terms of its components and relate the components to the different vendors in the market. The following infrastructure elements are necessary for ASPs: (1) technology for development, deployment, and management; (2) software; (3) delivery infrastructure for data needs; (4) business activities for establishing and managing ASP customer relationships; (5) communications networks; and (6) end users.

The hardware and software necessary for application development and deployment are technologies necessary for ASPs. These technologies can come from other software and technology companies that act in partnership with the ASP. Application software meeting business needs, such as ERP, can come either from ISVs or from ASPs. The delivery infrastructure must ensure the bandwidth capabilities both at the user and the vendor ends. In addition, the delivery infrastructure must ensure the data security and data center services such as proper backup and restoration.

Sometimes the ASPs are not capable of providing these services by themselves. In such cases, the ASPs may have to work with other software infrastructure partners who provide data center services or provide the necessary bandwidth. For example, initial customer-vendor relationships are established through marketing and sales. Once the initial contacts are established, there are other activities that must be performed. After the vendor and the customer enter into an agreement through the contract there will be a necessity for after-sales services such as customization, billing, and maintenance. ASP aggregators often offer these after-sales services to other ASPs. The ASP network infrastructure can be provided by ISPs or other third-party network service providers in the case of WAN architectures other than the Internet. Along with the networking elements, it often will be necessary to have services for

managing the networks to ensure optimal performance to meet an application's run-time needs and user needs.

Kern, Willcocks, and Lacity (2002, Netsourcing) present these elements in a similar manner by focusing on the service provided by networking alone. They use the term *netsourcing*, which they broadly define as provisioning of IT infrastructure services over networks, to refer to this service; it includes ASPs (Kern et al. 2002). Their definition of the netsourcing stack consists of the elements or components in an ASP. The components are: (1) network connectivity services, (2) network services—monitoring and management, (3) hosting infrastructure services, (4) application operating infrastructure services—middleware for remotely accessing applications, (5) standard application access services, (6) customized application access and support services, and (7) business process delivery services.

DETERMINANTS OF CUSTOMER ASP CHOICE

In the early days of ASP, the ASP market did not grow as anticipated. Not all companies considered ASPs to be an appropriate means for obtaining application software services. In particular, large companies often did not use ASP services. Thus, many of the ASP vendors targeted small and medium-sized enterprises (SMEs). Researchers have shown the suitability of ASPs for SMEs (Currie and Seltsikas 2001). SMEs may not have enough resources to set up their own applications, delivery infrastructures, and data centers. For SMEs, renting applications from service providers can be less costly than setting up their own facilities. Suitability of ASPs for SMEs does not

imply that large companies will not benefit from ASPs. Large companies also may find applications and requirements that ASPs can fulfill because of the variety of ASPs on the market. For example, a large company may not find that an ASP reseller meets the company's needs because of its large user base. Yet it may find an ASP that can provide application services required by a specific group or an organizational unit within the company. Table 1 shows a set of potential determinants for using an ASP's services.

Often, companies compare the costs of developing and deploying application software internally to the costs of renting the application from an ASP reseller or a developer. Nevertheless, factors other than costs must be considered when determining the use of ASPs (Jayatilaka, Schwarz, and Hirschheim 2003). The factors acting as determinants for using ASPs are cost advantages, availability of external resources, lack of internal resources, strategic reasons, and business knowledge associated with the application.

Implementation of application software is a task that can be costly and complex. According to the traditional systems development method, a software or systems life cycle consists of the following stages: preliminary investigation (including feasibility analysis), requirements analysis, design, development, testing, and maintenance. Prior to developing software, systems developers go through requirements gathering, analysis, and design stages regardless of the approach they use for development of the software. Once these activities are performed, actual software development (writing the code and testing) may require technical and human resources as well as financial resources, which are needed for acquiring and using other resources. After development, the software has to

Table 1: Possible Determinants of an ASP Choice

Determinant Category	Associated Determinants
Cost	Applications development
	Capital costs for infrastructures—servers, data centers
	Management costs—server management, data-center management, and some of the communications network management
	Maintenance costs—server maintenance, data-center maintenance, and some communication network maintenance
	Operations costs—data-center operations
	Support staff—application maintenance and help desk
Internal resources	Lacks personnel for development and supporting applications
	Lacks hardware, software, and networking resources
	Inability to keep up with the rapid changes in technologies
External resources	Needed applications, technologies, and vendor for obtaining application services available in market
	Rapid changes in technologies
Strategy/competition	Need for timely entry into a market/product/service
	Gain efficiency over competitors

be deployed and made available to the users in the operations and production stage. Once the application is in production, it needs to be properly managed for optimal effectiveness and efficiency. Making the application accessible over a company's network will require a network infrastructure, which includes communications software and hardware, server hardware and software, personnel for installation of the application, and operation and management of the network. If a company performs all these activities internally when implementing the systems, the company also has to manage the development and deployment process.

Essentially, a company has to incur technical, personnel, operational, and managerial costs for development and deployment by an internal IT department (often referred to as in-house development and deployment). However, if a company rents the application from an ASP, the company will not need to spend capital on development, deployment, management, and maintenance of the application. Providing help to the users is another essential task when an application is implemented within a company. In addition to the application costs, costs due to the server, data, and networks must be taken into consideration. Those costs are: (1) server management and maintenance, (2) data center management and maintenance, (3) data center operations, and (4) communications infrastructure management and maintenance. The applications must run on servers accessible to the users in a client company. Data generated through the use of the application must be properly maintained and managed. Proper management and maintenance requires making regular backups and allowing proper access to data. In addition, the servers and the networks delivering the application to the users must be managed and maintained.

Even if a company decides to use an ASP, the company still has to spend money for doing a preliminary investigation, gathering requirements, and analyzing and determining the specifications. The specifications of the needed systems may be found only during the design of business solutions. Once these initial activities are completed, the company will be able to find a suitable application package in the market and find an ASP that offers those application services. If the overall costs of in-house development and deployment of the application is higher than renting it from an ASP, a company may consider renting from the ASP. Although the cost is a primary determinant for many companies to choose an ASP vendor, it is advisable for them to consider other factors as well.

From a resource viewpoint, application development, deployment, and management consume scarce resources. Two essential types of such resources are technical and human. Even with the necessary financial resources, a company may not have the necessary technical resources or may not want to allocate existing resources to implement an application. As a possible scenario, consider a company that does not have a server capable of supporting an application with a large user base. If the installation and management of a new server requires more technical and personnel resources, the lack of resources presents a resource gap, and the company may have to seek the resources from an ASP vendor.

Vendors with the capabilities must exist in the market for a company to obtain application services. As discussed earlier, the services may need to come from more than just one vendor who can provide all the necessary infrastructure and services. The application may have to be obtained from one vendor (i.e., an ASP developer or reseller), while the hosting services and data center services may have to be obtained from another or the same vendor. Meanwhile, networking services such as the infrastructure and management services may have to be obtained from yet another vendor. Alternatively, it might be possible to obtain all the services from a single ASP. Whichever arrangement of sources is sought, the necessary capabilities must be available in the market. Then the costs of obtaining these available capabilities from the market must be evaluated. On the other hand, a company may already have some in-house capabilities and skills and thus be able to deliver the same application. In this case, it will be necessary to evaluate and compare the costs of using the internal resources versus the costs of using an ASP vendor. In some cases, a resource gap may exist, and a company may try to acquire the resource to implement the application. The estimated in-house costs will have to include acquisition of the needed resources as well.

Data communications and other information technologies are changing at a rapid pace because of innovations. With the rapid pace of change in the technologies, decision makers may perceive a rapidly diminishing effectiveness in their in-house software applications. They may find it necessary to upgrade the technologies frequently. In contrast, if a company obtains the services from an ASP, the burden of upgrading the technologies as the innovations occur shifts to the vendor. The vendor will be in a better position to perform the necessary upgrades to their applications and the associated technologies because they are directly related to their core competency. Therefore, if a company wants to mitigate the risks of technological obsolescence or diminishing effectiveness due to rapid changes in technologies, the company may seek the services of an ASP.

Cost and unavailability of resources are not the only drivers for using an ASP. A company may have a need for an application implemented by its competitors as well. When a short time for implementing the application is a critical factor, a company may find it quicker to obtain the services of an ASP. An ASP may be able to offer the application more quickly to better support the company's strategy. Sometimes a company may have an application that performs efficiently with a quick response time. For example, in order to support a large sales force in the field competitively, it may be necessary to have an application that provides quick responses to sales personnel's requests. An in-house IT department may not be able to provide the high performance needed, whereas an ASP may be able to provide the application services at the performance level required. Therefore, in this case the ASP will be able to support the competitive advantage through its sales-force support application. Of course, when considering the strategic importance of an application, an ASP may not always provide a strategic advantage. Although a vendor offers a strategically important application, renting an application from an ASP may involve risks also. The next section examines this risk from ASPs.

RISKS IN ASPs

Several risks are associated with the use of ASPs. However, knowing the potential risks can help both vendors and customers to mitigate those risks. Sometimes the risks may be considered as disadvantages at an aggregated level (NTAP 2006), but the risks can arise for several reasons. Because of the different types of risks, the risk factors must be considered individually, and proper analysis of these risks is necessary (Kern et al. 2002, Application service provision). There are organizational risks and technical risks. In some situations, these two types of risks may need a comprehensive approach. Although some risks are primarily technical in nature, some need proper organizational as well as technical solutions. Table 2 shows the risks associated with ASPs and their two primary categories—technical and organizational. This categorization attempts to make it easy to identify the risks.

Security of data, or the lack of security, is one of the major risks of ASPs. In the ASP model, customers' data are stored at the vendor's data center. The vendor is responsible for management of the data, and the vendor has more control over the data. The customer risks loss of confidential company information or specific business processes of the company. In some cases, the data resulting from the use of an application may divulge information about the business processes of the customer company. Therefore, the security of the data is a critical issue that

must be taken into consideration. Data security has to be ensured at two stages of the application-use process: (1) when data are transmitted over the networks, and (2) when the data are archived or stored at the data centers. If customer data are strategically critical and security is essential, security must be guaranteed all the time. During the initial customer vendor negotiations, it is necessary to discuss how the data will be secured by the vendor and what guarantees the vendor can provide about the security of the data. Some of the specific important aspects of security are: (1) access privileges, (2) access controls, (3) data transmission security, (4) disaster management, (5) intrusion detection and reporting, and (6) communication of data security status to customers.

One critical technical risk is the poor performance of the application itself. The performance of an application depends on the network performance as well as the software performance. Network performance is often defined in terms of measures such as response time, availability, reliability, and throughput. From the customer view, users must be able to get fast responses and the applications must be available when they are needed. ASPs must be able to provide information on their performance related to specific applications. Such prior knowledge about the ASP's performance will help clients mitigate future risks due to poor performance. One method to mitigate the risk due to poor performance is to implement proper

Table 2: Risks Associated with ASPs

Category	Risk	Mitigation
Technical	Data security • Lack of secure transmission channels • Lack of security at data center and data resources not properly secured	Proper analysis of vendor and network service provider capabilities and technologies Ensuring the following are clearly specified, understood and agreed to by vendors and customers: • access privileges • access controls • data transmission security • disaster management • intrusion detection and reporting • communication of data security status to customers
	Performance—inadequate or not meeting expectations	Proper analysis of vendor and network service provider capabilities and technologies
	Failure of systems	Determining the tolerable failures Ensuring that proper procedures for recovery are in place
Organizational	Data security—possibility of application data divulging strategically important information to competitors through the vendor	Inclusion of necessary conditions, procedures, and policies in the contract
	Vendor going out of business	Evaluating tenure and past performance of the vendor before selecting
	Vendor not performing as expected	Contract stipulations and monitoring
	Vendor subcontracting	Include in the vendor negotiations
	Customers' unrealistic expectations	Educate customers about capabilities, problems, and risks
	Customer immaturity/lack of knowledge	Same as above

monitoring and management of the networks and servers so that optimal performance can be obtained (Fitzgerald and Dennis 2005; Goldman and Rawles 2004).

Failures of network and server are technical in nature; however, they are risks that are similar to the other issues to be foreseen and prevented. Organizational mechanisms must be put in place to mitigate the risks due to failure. Any system, server, or network is subject to failing or crash. However, it is necessary to take appropriate steps to recover from failure and minimize the damage or problems due to failures. To avoid failures of servers, fault-tolerant systems and duplicate systems can be used. Similarly, the networks can have duplicate resources to handle a failure. Yet having redundant resources can be too costly sometimes; fail-proof services may not always be required. In such cases, it will be necessary to bring up the applications properly after a failure and restore the data so minimal disruptions occur in the business processes.

Other major risks are due to organizational and managerial issues (Kern et al. 2002, Application service provision). ASPs may oversell their capabilities, knowingly or unknowingly. This risk can be mitigated by properly analyzing the ASP proposals and capabilities prior to signing the agreements. As we saw earlier, the breadth of players in the ASP arena may result in the possibility of the primary provider subcontracting some tasks of an ASP arrangement to other vendors. Subcontracting can give rise to problems (Kern et al. 2002, Application service provision). Therefore, the customer company should make sure to identify the subcontracts within an ASP and to evaluate their performance and records prior to deciding on a specific ASP. Just as in any other product, a risk exists because of the possibility of a vendor going out of business. Sometimes, because of turbulent times, this failure may not be predictable. Nevertheless, it is better to be aware that such a likelihood exists. Customers should gather information on the tenure of the vendor and their past performance. Such information on the vendor may provide some indications of the likelihood of failure. From the customer side, the risks can occur because of a customer's unrealistic expectations, getting into incomplete contracts, and lack of experience of the customer (Kern et al. 2002, Application service provision).

FEASIBILITY ASSESSMENT OF ASP— MAKING A BUSINESS CASE

Every company should perform a complete feasibility analysis before deciding on an ASP. The feasibility analysis must include economic feasibility, technical feasibility, operational feasibility, and legal feasibility. Other feasibilities may be considered, depending on the business/organizational or market conditions. In some cases, it may be necessary to consider political feasibility in certain countries or in certain organizations before using an ASP. The technical components, risks, and the business model discussed earlier in this chapter must be considered when examining the technical feasibility. Basically, a company needs to evaluate whether the technologies necessary for the application and delivery of services as required are available within the organization or if they should be outsourced. Operational feasibility involves determining whether it is possible to use the ASP services within the company's operational context. This section examines factors necessary for evaluating economic feasibility and other nonfinancial factors that impact technical, operational, and other feasibilities.

Economic feasibility is the examination of the cost-effectiveness of the ASP. As discussed earlier, the costs of using an internal IT department and the ASP must be evaluated and compared. These cost factors will be incurred in internal sourcing and usually this can be called the total cost of ownership (TCO) of an application. Cost comparisons for internal sourcing of applications and using external ASP services are shown in Table 3, which shows costs as static factors; however, it is also necessary to consider the expected period of the use of the ASP application. For example, the cumulative cost of renting ASP software for the expected period of use must be calculated.

The other factors are not directly related to the costs and may not be financially quantifiable. Organizational level factors that need to be considered are as follows:

- Specificity of the application (Does the ASP offer customization?)
- Ability of the ASP to serve the user base in the company
- Need for control of the application
- Strategic importance of the application

Table 3: Costs to Be Included in an Economic Feasibility Study

Cost of Internal Sourcing	Costs of Using an ASP Vendor
• Analysis costs • Total cost of ownership: – Application development or purchasing cost – Server costs: initial purchasing, management and/or maintenance – Network costs – Application maintenance costs – Data center costs	• Analysis costs • Rent and other fees • External network use costs—delivery infrastructure (Internet or other WAN) • Early termination fees & costs to be incurred due to risks (not always) • Vendor relationship management costs

- Time criticality of the application services
- Need for integration with the rest of the organization
- Need for focusing on strategic or core activities rather than implementing the application in-house.
- Handling of failures and recovery policies

At the individual user level, the following factors need to be considered:

- User interfaces—commonly used Internet browsers or application specific interfaces
- User training (Does the ASP provide training?)
- User support—availability of help-desk facilities
- Customer service in general

In addition to the above, a business or organization may have questions that are specific to that organization's context. The topic of feasibility analysis of ASPs is extensive, spanning the feasibility of IT in general. As such, this section is limited to pointing out the important factors.

CONCLUSION

Obtaining an ASP's services shows marked differences from traditional outsourcing because of its dependence on computer networks, although both types of sourcing use external vendors to obtain IT services. ASP is limited to application-software services only, whereas traditional outsourcing covers the whole range of IT activities. Because of the cost benefits provided by ASP arrangements and the capabilities of vendors, many companies will seek ASPs to obtain application services. Because of the ability of an ASP to serve many customers, an ASP will have the advantage of the economy of scale and will be able to provide solutions to customers at an acceptable cost (i.e., at a cost lower than if the customer were to develop and host its own application). Also, a vendor may have the technical expertise to implement and manage network applications. In particular, the development and broad availability of networking technologies are making ASP arrangements more attractive than ever before. Today's networks carry more bandwidth, provide better security, and will continue to improve in the future.

Researchers have been examining the ASP phenomenon, but it is not as extensively researched as traditional outsourcing (Dibbern et al. 2004). ASP can be treated as an evolutionary step in the traditional outsourcing (Currie and Selstikas 2001; Tebboune 2003). This chapter presented the basics of application service providers. When deciding whether to use an ASP, it is necessary to consider the factors applicable to the specific business/organizational context and to evaluate the available vendor services properly (Currie et al. 2004; Jayatilaka et al. 2003). For clients to see the fit between business needs and benefits of an ASP, the client's evaluation of their needs is inadequate. The vendor must give appropriate value propositions to the clients (Currie 2004; Currie et al. 2004). The vendors will be able to provide clients with appropriate value propositions if they understand the clients' needs properly. Therefore, the vendors' perceptions of the clients are critical.

GLOSSARY

Application: A computer program used by an organization to perform tasks to achieve a given objective.

ASP (Application Service Provider): A vendor providing application services to customers for a fee.

ASP (Application Service Provisioning): Act of providing application services for a fee.

Enterprise ASP: An independent software vendor who deploys their own application to deliver the application services directly to the customers.

Feasibility Assessment (ASP Feasibility): Determining whether the use of an ASP can be done with the available technologies and whether vendors are available with the necessary capabilities. Different feasibility categories include economic feasibility, legal feasibility, operational feasibility, political feasibility, schedule feasibility, and technical feasibility.

Horizontal ASP: A vendor who provides an application service that cuts across industries but is specific to a given application—e.g., e-mail.

Netsourcing: Obtaining IT services over computer networks.

MSP (Managed Service Providers): A vendor who provides a variety of managed services, sometimes including application services. These types of vendors also provide other services such as network management services.

Pure-Play ASP: A vendor who takes on the responsibility for all of the requirements for delivering the application services.

Vertical ASP: A vendor who provides all of the applications required by a specific industry.

VPN (Virtual Private Network): A secure network established over a public network such as the Internet or over a more open wide area network. This network is called "virtual" because only a secure channel is provided over an existing physical network, while no separate physical network exists for the private network.

WAN (Wide Area Networks): A network that spans more than a single building or work area.

xSP: An abbreviation referring to service provisioning in general.

INTRODUCTION

Videoconferencing has been widely hailed both for its incredible potential to change the way we work and interact as well as for its arguably ongoing failure to actually live up to that potential (Egido 1988). The myriad potential uses of videoconferencing that have been touted over the years include:

- *Interpersonal communication:* This use of videoconferencing extends the traditional telephone model with video.
- *Business meetings:* By connecting multiple individuals or small groups located in different offices, videoconferencing can potentially provide greater flexibility to employees in terms of where they conduct business as well as potentially reduce costs to employers by eliminating the need for relatively expensive and slow business travel.
- *Distance learning:* Videoconferencing could allow educators to meet interactively with remotely located students either individually or as a group. Descriptions of videoconferencing in a distance learning setting often include the integrated use of other collaboration tools such as online whiteboards and shared document editing.
- *Telemedicine:* By allowing doctors to consult interactively with other doctors and patients, videoconferencing could potentially improve access to health care for rural areas where access to expert care is otherwise limited and cumbersome.

Although videoconferencing is used more widely than ever and that use is growing, there is still a gap between its real and potential impact. The exact reasons for the failure of videoconferencing to become the next “killer app” are difficult to distill, and there is little to no consensus among developers or potential users as to what obstacles remain. It may be a matter of usability and thus point toward

issues of user interface and session management. Alternatively, it may be a larger-scale social issue of how people interact with visual images, in which case the future of videoconferencing may lie in improving the sense of presence created by videoconferencing technologies. Videoconferencing may fall into a natural dead spot between the need to communicate quickly, satisfied by e-mail and telephony, and the need to communicate more deeply and spontaneously over longer timescales, satisfied by actually traveling in order to be physically co-located. Or it may simply be a matter of time before we find that videoconferencing does live up to all our expectations. Whatever the reason, videoconferencing remains an important application area both for its current growing impact and its future unrealized potential.

What makes videoconferencing a particularly interesting technical case study is that almost all of the difficult technical issues have largely been solved. Although early videoconferencing systems suffered from a lack of processing power at the client end and limited end-to-end bandwidth, advances in processor speeds and the wide-scale deployment of broadband networks have obviated many of these resource limitations. A notable exception is the failure of Internet protocol (IP)-based multicast that would have greatly enhanced the development of many videoconferencing systems.

A simple definition of videoconferencing is that it is an application that allows two or more remotely located participants (or groups of participants) to communicate in real time using video and audio. It is important to draw a distinction between video conferencing and video streaming and voice over IP (VoIP) telephony. Clearly, elements of both of these other application domains exist within the domain of videoconferencing. The difference between conferencing and streaming revolve mostly around the latency requirements of conferencing. Although streaming applications can often afford a startup delay of several seconds in order to provide spacious buffers for smooth and synchronized video delivery, the

same is not true in a conferencing application. Another important difference is that each participant both produces and consumes a number of media streams.

The main difference with IP telephony is the addition of a video stream that generally dwarfs the associated audio stream in computational complexity and bandwidth requirements. Both application domains require session control and setup protocols. In fact, there is little in these session-control protocols that is video-specific, and our treatment here will omit discussion of session control altogether to avoid duplication with other chapters that deal with VoIP as an application. Both the H.323 standard published by the International Telecommunication Union (ITU) and the SIP standard published by the Internet Engineering Task Force (IETF) are widely used for both VoIP and videoconferencing (ITU 2006; Rosenberg 2002).

In this chapter, we examine a number of aspects of videoconferencing. Although usability and interface issues may be the key for harnessing the untapped potential of videoconferencing as an application, our goal here is to concentrate on the technical aspects of the application. Thus, we focus our attention on its technical challenges and the current state-of-the-art solutions for IP-based videoconferencing. We begin with a brief history of various notable videoconferencing systems that have been developed over the years. We then discuss the various human factors involved and the requirements these factors place on videoconferencing systems in general (especially with regard to end-to-end latency limits). A taxonomy of different videoconferencing architectures is presented to provide an overview of the design space and to provide context for many of the technical challenges. Following this, we include sections that focus on the networking and video-encoding aspects of videoconferencing. A brief section describing various audio standards follows. Finally, the chapter concludes with a discussion of the future of videoconferencing and current research efforts in tele-immersion. Throughout this chapter, the focus of our attention is on IP-based videoconferencing via the Internet.

HISTORY

Early videoconferencing systems dating back to the late 1960s and early 1970s were largely developed as extensions of the telephone. AT&T and Ericsson both demonstrated video phone products in the late 1960s and early 1970s. Neither was able to attract much commercial success. Large companies began to develop in-house analog videoconferencing capabilities between dedicated meeting rooms as way of facilitating remote collaboration in the 1970s. Notable efforts include those of Nippon Telegraph and Telephone and IBM. These were closed systems that were engineered and developed for specific sites and were not developed as commercial products.

The first reasonably successful commercial product was the PictureTel system introduced in the early 1980s. This system included dedicated hardware operating over leased lines and at \$80,000 was remarkably expensive (although much cheaper than any other solution at the time). As PictureTel continued to develop and improve

its product, costs were lowered and quality improved. By 1991, a PictureTel system could be purchased for approximately \$20,000 with \$30/hour line charges. PictureTel systems were marketed to businesses and were typically installed in meeting rooms as a way of connecting groups of people.

With the development and deployment of the Internet, videoconferencing for individuals using digital packet video and audio on a PC became a reality. The CU-SeeMe system developed at Cornell University in 1992, however, was the first system to really tap into the potential of videoconferencing on the Internet (Dorcey 1995). Although the video quality provided by CU-SeeMe was very limited (initially 160×120 4-bit grayscale), the system benefited tremendously by the fact that the program was free. This allowed ordinary users, developers, and enthusiasts to experiment with videoconferencing. CU-SeeMe was developed first for the Macintosh, and a Windows version followed within a few years.

At around the same time, development of IP-multicast and the initial deployment of multicast via the MBone led to the development of a number of UNIX-based videoconferencing systems. These systems were largely experimental research systems and included NetVideo or *nv* from Xerox PARC (Fredricks 1992), the INRIA Videoconferencing System, also known as *ivs* (Turletti 1994), and LBL's suite of videoconferencing tools *vic*, *vat*, and *wb* (McCanne and Jacobson 1995), which, respectively, provided videoconferencing, audio conferencing, and shared whiteboard functionality. All of these systems are notable for their pioneering use of the real-time protocol (RTP) and the real-time control protocol (RTCP) developed within the Audio/Video Transport working group of the IETF.

In conjunction with the development and use of these research systems, standards were developed to address various facets of videoconferencing. These included various standards for video codecs such as H.261, H.263, and more recently H.264; audio codecs such as G.711, G.722, and G.728; and session control such as H.323 and SIP. The standards process is particularly important for videoconferencing as an application domain in order to promote interoperability among different systems.

Low-cost standards-based commercial desktop videoconferencing emerged in the early 1990s with Intel's ProShare system and Microsoft's NetMeeting. Since then, the number of IP-based desktop videoconferencing solutions has exploded, and any number of commercial, freeware, shareware, and open source solutions are available (Woolley 2006). NetMeeting is now bundled with Microsoft's WindowsXP operating system. Similarly, Apple bundles a version of their videoconferencing system, iChat, with the OS X operating system. The availability of feature-rich, standards-based videoconferencing as part and parcel of the standard software delivered with the operating system is further evidence of the maturation of videoconferencing as an application. Recently, Skype has received a great deal of attention as a peer-to-peer VoIP and video conferencing solution (Krim 2005). The main technical innovation of Skype is its very robust and turnkey handling of network address translation (NAT) devices.

HUMAN FACTORS

The effectiveness of videoconferencing is determined by the user's perceived quality of the experience. This in turn is directly related to a number of different human factors governing the utility of both the video and audio channels and the overall usability of the system. In this section, we highlight several of these factors, including communication latency and jitter, audio quality, video quality, intermedia issues, and usability.

Latency

Latency is generally considered the number one factor in determining the perceived quality of a videoconference. It has been shown that the effects of latency on interactive communication is noticeable as latency exceeds 100 msec, is significantly disruptive as latency approaches 250 msec, and is crippling as latency exceeds 500 msec (Krauss and Bricker 1967). Thus, latency control is a key issue for videoconferencing systems. Another factor affecting the perceived quality of video is media jitter. In general, smooth delivery of video frames at an even slower rate is perceived as being of higher quality than delivery of video frames at an uneven higher frame rate (Calyam et al. 2004).

Quality Metrics

Although the audio stream portion of a videoconference consumes significantly less bandwidth than the video portion, paradoxically, it is generally much more important to the overall quality of the video conference and can be much more sensitive to dynamic network conditions. From a human factors point of view, however, the quality requirements imposed on the audio stream are quite modest, as the audio content for a video conference is most often human speech. Thus, basic telephonic audio transmission rates and fidelity suffice to support most communication needs.

The relationship between video quality and the overall quality of experience provided by videoconferencing is much more difficult to determine. This is because assessing the impact of video quality is greatly affected by the metrics used to measure the quality of the conference itself. If the metric used is too simplistic (e.g., were participants able to effectively communicate some specific piece of information), the value of the video channel as a whole may be negligible or the effect of video quality may be immaterial. In other words, even though the metric is well defined and easy to quantify, the metric may be measuring a quality that is not greatly influenced by the visual information provided by the video channel. If, instead, one focuses on the value of nonverbal communication such as the ability to express understanding (e.g., nodding or shaking one's head), interest level (e.g., smiling, attentiveness), or gestures, the quality of the video channel becomes much more important (Isaacs and Tang 1994). Often, this nonverbal communication is described as the "sense of presence." One can qualitatively judge the sense of presence created by a videoconference relative to the experience of actually being physically co-located, but quantifying this sense of presence and deriving a

relationship of it to analytical measures of video quality (e.g., peak signal-to-noise ratio or frame rate) remains very difficult.

Audio versus Video

As a rule of thumb, audio is more important to the basic communication needs of videoconferencing participants than is video. A videoconference in which the video channel ceases to function essentially (and automatically) becomes the same as a telephone call. A conference in which the audio channel ceases to function, on the other hand, becomes almost meaningless. Another intermedia issue is that of synchronization. Whereas synchronized delivery of video and audio certainly benefits the perceived quality of both channels, doing so may be to the detriment of end-to-end latency.

Usability

The usability of a videoconferencing system in large part reflects the culture of the organization and whether the conference is being used to support informal, interpersonal communication or more formal, intergroup communication. Videoconferencing as an informal, interpersonal communication channel requires an organizational culture that provides the necessary equipment and resources to enough people such that a critical mass is achieved and people can expect to communicate via conferencing (Fish et al. 1992). Usability and effectiveness in such a setting can then be measured by examining the circumstances in which participants choose conferencing instead of other communication methods such as e-mail and/or the telephone. Conferencing for intergroup communication is often realized by constructing specific meeting rooms in which conference facilities have been installed. Usability in these settings is dominated by ease of setup, configuration, and control.

CONFERENCING ARCHITECTURES

The architecture of most IP-based videoconferencing systems is primarily organized in one of two ways. The first is a centralized architecture in which all media data are sent from all conference participants to a single location and then rebroadcast to participants. The second is a decentralized architecture in which participants distribute their video and audio streams directly to each other. This section describes each of these architectures in greater detail, noting their relative strengths and weaknesses. A noteworthy special case is a videoconference that involves only two participants. In this case the participants directly exchange media streams. Although this situation can be clearly classified as an instance of a decentralized architecture, it can almost as easily be considered an instance of a centralized architecture in which one of the participants is deemed a "master" to the other. The difference in this case is purely one of semantics.

Centralized

A centralized conferencing architecture relies on the existence of a single rendezvous point to serve as the destination

Figure 1: Logical relationships between participants and an MCU in a centralized conferencing architecture

for all of the media streams produced by all participants and is the source of media streams received by participants for display to the user. Such an architecture is illustrated in Figure 1. A common name for this centralized service is a multipoint control unit (MCU). Although it is conceivable that the MCU may in fact be co-located with one of the participants, in general the advantages of a MCU-based architecture are more easily realized if this service exists within the networking infrastructure on a well-provisioned host or as a special-purpose device dedicated to the task. The MCU is responsible for synchronizing the media streams from each participant and redistributing one or more media streams to the participants for presentation.

There are a number of advantages to a MCU-based architecture. First, the MCU can synchronize and mix together all of the audio streams into a single, coherent audio stream. This ensures that all participants hear each other in the same way. This is particularly important if the audio levels of different participants vary, since the MCU can then normalize the different streams by applying a participant-specific gain function. Second, if conference participants are able to reasonably receive only a limited number of video streams because of bandwidth considerations, the MCU can effectively negotiate competing interests and ensure that each participant is watching the same stream in order to realize a measure of floor control. Third, if the conference participants have heterogeneous capabilities, the MCU can tailor the streams distributed to participants in order to match client capabilities. Fourth, the MCU provides a convenient billing model for third-party conference services that may require differential pricing based on the number of participants and/or duration of the conference. Finally, the MCU provides a convenient framework within which to implement security and authentication measures if the media streams require encryption.

Decentralized

A decentralized conferencing architecture relies on the participants themselves to distribute the media streams directly to each other as peers, and in fact videoconferencing is an early example of a peer-to-peer application, even

predating wide use of that term. Such an architecture is illustrated in Figure 2. A decentralized architecture is best suited for participants that are reasonably homogenous in client capabilities and network connectivity. As will be discussed in more detail later, the availability of multicast can greatly facilitate the effectiveness of a decentralized approach. One advantage of a decentralized approach by definition is that it does not rely on the deployment and availability of an MCU infrastructure. A second advantage of a decentralized approach is the ability to optimize each media stream for the dynamic network conditions that may exist between participants on a pairwise basis. This may be especially important if one of the participants is located relatively far away (e.g., on the other side of a long-latency satellite link) from the other participants. A third advantage is that the decentralized approach provides more flexibility to individual users in determining exactly which media streams to receive and display and to whom their own media streams are distributed.

Decentralized or peer-to-peer architecture requires all-to-all distribution of media streams. Limiting number of sources via floor control and using multicast can alleviate communication burden.

NETWORKING ISSUES

This section reviews a number of networking protocols, mechanisms, and techniques that are important to videoconferencing systems. Because other chapters in this volume deal with many of these same topics in greater depth, the treatment here concentrates on how these concepts specifically relate to videoconferencing as an application. General descriptions of protocols that are covered elsewhere in this volume will be kept brief and informal in order to provide only the context necessary.

Multicast

Multicast is a natural fit for multiparty videoconferencing and can greatly improve a system's ability to scale to accommodate more participants. As originally envisioned, IP multicast establishes per group state in the routing infrastructure in order to discover and maintain a source-specific distribution tree spanning the participants of a multicast (Deering 1988). A class D IP address is used to address the multicast group. A host controls membership in an IP multicast group with `join` and `leave` messages that update the distribution tree accordingly. Packets addressed to the group traverse the distribution tree with routers replicating the packet as necessary at branch points.

The service model associated with IP multicast is strictly best effort, with no guarantee of delivery. Without application-level feedback, IP multicast does not provide the sender with any information about whether a packet was delivered to all, none, or some subset of the participants. Neither does IP multicast maintain any sort of group membership list. In fact, any number of hosts can act as sources of packets for an IP multicast group, and a source is not required to join the IP multicast as a participant.

Although powerful, IP multicast has proven difficult to deploy. In part, this has been due to a number of technical challenges inherent in multicast routing and tree maintenance. To address some of these challenges, later developments of IP multicast introduced the idea of single-source multicast (Holbrook and Cheriton 1999). In single-source IP multicast, the root of the distribution tree is placed at a single host that is the only source of packets allowed for that particular multicast group. Single-source IP multicast greatly simplifies routing and tree maintenance, does not require periodic flooding of multicast packets as occurred in the original IP multicast service, and allows group size and membership to be more strictly monitored and controlled. Furthermore, single-source IP multicast provides a scalable way to solicit feedback from participants about dynamic network characteristics such as latency, loss, and jitter.

In a centralized videoconferencing architecture, unicast transmission can be used to send media streams from each participant to the MCU. The MCU, in turn, can send a composite result back to the participants via multicast. This is a particularly good fit for single-source IP multicast, since the MCU is the only component of such an architecture that requires the ability to send IP multicast packets. Furthermore, the MCU can leverage the feedback facilities of single-source IP multicast to

monitor performance in order to group participants by the quality of service experienced. This allows the MCU to tailor the encoding and transmission of the media streams (e.g., lowering video quality or frame rate for bandwidth-constrained hosts) to best fit the encountered conditions.

In a decentralized architecture, a multicast group can be associated with a particular media type (i.e., one group for all video information from all participants and one group for all of the audio), a particular participant (i.e., each participant creates one multicast group for distributing its video and its audio), or both. The capabilities of the multicast service available will obviously constrain the design choice. For example, if single-source IP multicast is being used, then grouping media by type is not an option. Although soliciting feedback from participants and dynamically grouping participants by loss and latency characteristics is possible in a decentralized system, the complexity of doing so is greatly increased by the fact that every participant is also a source of multicast packets.

Sadly, IP multicast, either in its originally envisioned form or single source, is likely never to be widely deployed on the Internet at large. The barrier to deployment has little to do with the technical challenges faced but instead seems to revolve around economic issues that result in very little incentive for Internet service providers (ISPs) to deploy multicast. Despite this, multicast is still a viable option for intranets within an organization that enjoys full control over its administrative domain. For organizations with a number of different locations, the combination of virtual private networks (VPNs) and locally administered IP multicast can be used to support videoconferencing within the organization. Another option is to rely on the services of a content distribution network (CDN). A CDN is an overlay network established by third-party organizations that is distributed across many different ISPs with nodes strategically located at various peering points (Verma 2002). Multicast can then be implemented as a service within a CDN.

Furthermore, in the past several years a number of application-level multicast technologies have been developed. Application-level multicast (ALM) does not rely on router support for maintaining the distribution tree and replicating packets. Instead, the participants themselves are organized into a distribution tree and packets are unicast in a peer-to-peer fashion (Banerjee, Bhattacharjee, and Kommareddy 2002; Chu et al. 2001; Zhang and Hu 2003; Kostić et al. 2003; Ratnasamy et al. 2001). ALM schemes are often evaluated in terms of stress and stretch (Chu, Rao, and Zhang 2000). Stress is defined as the number of copies of a particular packet that must traverse an underlying physical link given the ALM distribution tree that is created. *Stretch* measures the ratio between the costs (generally in terms of latency or hop count) of the path from source to a participant in the ALM scheme compared to the direct unicast path between those hosts.

Several issues must be addressed if an ALM scheme is to be used for videoconferencing. Because videoconferencing is very sensitive to latency, managing stretch will be a prime concern. Since the number and location of

participants in a video conference is usually reasonably stable, much of the complexity of ALM protocols for dealing with participants joining and leaving, also known as *churn*, may be avoided by precomputing an optimal distribution tree of the known participants and tailoring with as much knowledge about client capabilities and available bandwidth as possible. Since each peer will now be responsible for replicating packets for one or more children in the distribution tree, limiting the number of such media streams that need to be distributed will probably be necessary. This implies that floor control should be done in a centralized manner to select the media streams to be distributed to all participants.

Jitter Control

Jitter can be defined as the variance of the interarrival separation of a stream of packets. In other words, jitter is a measure of the latency variance experienced by packets transmitted through the Internet. The primary cause of jitter is the dynamic growing and shrinking of queues encountered in routers along the forwarding path. Thus, while a stream of packets originally transmitted at an even rate can be expected to arrive at that same average rate over some sufficiently long time scale, at shorter time scales, the packet arrival rate will fluctuate.

A subtle, but important, distinction needs to be made between packet jitter and media jitter. For media data types in which the natural application data unit is quite small relative to packet size, many samples of the media are generally packed into a single packet. For example, the natural data unit for audio data is a single audio sample. In the case of a monaural representation, this may be as small as 1 byte. In this case, packet-level jitter manifests itself as jitter between frames of audio data, where each frame is a collection of audio samples. For media data types in which the natural application data unit is larger relative to packet size, a media data unit is necessarily fragmented into two or more packets. For example, video frames, even when compressed, often do not fit into a single packet. Typically the packets that comprise a single video frame are sent with little to no separation followed by a delay between the last packet of one video frame and the first packet of the next. In this case, packet-level jitter does not directly translate into frame-level jitter. A videoconferencing system is ultimately most concerned with media jitter. To the degree that media jitter is a function of and reflects packet jitter, we can discuss the issue relative to packet jitter without belaboring the point.

Controlling jitter is important because users are sensitive to the smoothness of media playback. To control jitter, videoconferencing systems use a jitter buffer, which essentially delays playback of a media data unit in order to ensure that the next media unit arrives by the time it needs to be played. This additional delay is often referred to as the playout delay.

Synchronized clocks are not necessary to measure jitter and determine playout delay. Instead, a method based on modeling the difference between two unsynchronized clocks can be used. In this method, each media unit is timestamped by the sending host with the system time of its transmission. Upon the arrival of the first media

unit, the receiving host calculates the clock offset as the difference between its system time and the time stamp carried by the media unit itself. This initial calculation of offset is shown in Equation 1.

$$\text{offset} = t_{\text{current}} - t_{\text{media}} \quad (1)$$

Using this offset value, the playout time in terms of the local system clock for this media unit and all subsequent media units is calculated using Equation 2.

$$\text{playout} = \text{speed} * t_{\text{media}} + \text{offset} \quad (2)$$

In this formula, the speed term represents the playback rate relative to the natural media rate. Values larger than one correspond to playing faster (i.e., fast forward) while values smaller than one correspond to playing slower (i.e., slow motion). For videoconferencing applications, this term is nearly always set to the value one. The value of offset models the end-to-end display latency. In our formulation above, this is initially determined by the first media unit, which, according to the formula in Equation 2, would be displayed immediately.

The key issue for this method is appropriately setting and adaptively changing the value of offset to accommodate dynamic network conditions. Naylor and Kleinrock (1982) first articulated the spectrum of choices for jitter buffers as lying between two policies that they call the "I-policy" and the "E-policy." The I-policy attempts to permanently set offset to a reasonably representative value and discards all media units that do not arrive by the calculated display times. At the other end of the spectrum, the E-policy resets the value of offset to accommodate the largest observed offset, ensuring that no subsequent media units that experience smaller delays will ever miss the calculated display time. Between the two extremes is any number of adaptive solutions.

Since offset models both the large-time-scale average network delay that the system must accommodate as well as an allowance for any small time-scale jitter, setting it based solely on the first media unit is insufficient, as the delay experienced by the first media unit may or may not be a representative value. Typically, offset is recalculated periodically as an exponential weighted moving average (EWMA) of the observed clock differences. Although this helps to smooth out the estimate for offset, the choice of gain coefficients of the EWMA filter still represents a design choice between an estimator that is very stable, but not particularly agile, and an estimator that is very agile, but not as stable (Kim and Noble 2001). Another technique is to recalculate the value of offset implicitly by monitoring the queue length of media units waiting to be displayed (Stone and Jeffay 1994). In other words, if the current value of offset results in a persistent queue of media units that arrive before the appropriate display time, offset is recalculated to effectively reduce the queue length.

Media elasticity is another issue that must be considered when designing an adaptive jitter buffer algorithm. *Elasticity* refers to the quality degradation associated with a media data type due to lost or discarded media units and/or presentation of those data units at a rate other than the

natural media data rate. For example, video is a highly elastic data type, since the marginal effect on perceived quality of a missing frame is low. Furthermore, video can be displayed either at a faster or a slower rate than its natural frame rate without greatly affecting quality. This sort of time dilation and compression is almost imperceptible if it is within 10 percent of the natural frame rate. Audio, on the other hand, is not particularly elastic. Missing audio samples cause highly perceptible pops and other annoying artifacts, and it is much more difficult to play audio frames at any rate other than its natural rate without either causing gaps between audio frames sent to the audio device, perceptibly changing the pitch of the audio, and/or causing audio samples to be destructively played on top of each other.

The elasticity characteristics of the media type determine to what extent jitter buffer adjustments can be made and when. Jitter buffer adjustments for video can be done at almost any granularity and at almost any time because they can be implemented by taking advantage of the elastic nature of video as a media type. The same cannot be said of audio. Instead, a common technique for videoconferencing in which the audio is almost always human conversation is to take advantage of talkspurts. A talkspurt is a sequence of audio frames that represent continuous talking by one of the participants. Generally, talkspurts are separated by some amount of silence created by the natural back and forth between participants in the conversation and/or thinking times and breathing pauses between statements. These silence periods can be lengthened and/or shortened without any effect on the perceived quality of the audio stream, and thus represent the best opportunity to make adaptive changes to playout delay (Moon, Kurose, and Towsley 1998).

Transport Protocols

The development of early videoconferencing systems such as the vic/vat suite was done in conjunction with efforts by the IETF Audio/Visual Transport Working Group to develop suitable transport-level protocols for such systems. The results were definitions for the real-time protocol (RTP) and its companion real-time control protocol (RTCP) (Schulzrinne et al. 1996). Although intended to be used together and to support multicast, multiparty applications, either protocol can be effectively used separately and in unicast environments as well. Both of these protocols continue to be used in media streaming applications of all sorts, including videoconferencing. Because these protocols are described in greater detail elsewhere in this book, we only briefly review their main design features here in the context of videoconferencing.

The design of RTP and RTCP is firmly grounded in the principle of application layer framing (Clark and Tennenhouse 1990). This design principle stresses the concept that the application is in the best position to understand how the underlying constraints of the protocol stack (e.g., minimum/maximum packet size, etc.) and network dynamics (e.g., loss, delay, etc.) affect the overall quality of experience within the application. Toward this end, hidden costs and constraints should be exposed to the application, which can in turn adapt how it represents

and frames data to achieve application-level goals. By applying this principle to the design of RTP and RTCP, its creators have purposefully underspecified many key elements of the protocol. Thus, the protocol specifications are incomplete and must be augmented with additional specifications to fill out the exact semantics of various header fields and the format and layout of data packets for a particular data type within the context of a particular application.

RTP provides a very thin header to support a number of basic media unit framing and transport tasks. The header includes the following fields:

- *Sequence number*: This 16-bit field is expected to monotonically increase, and numbers each packet in sequence in order to support loss detection.
- *Payload type*: This media-type-specific field identifies the data type encapsulated by the packet. The exact semantics of the time stamp field (described below) and the format and layout of data in the payload of this packet are determined by the value of this field.
- *Time stamp*: This field provides timing information for the media data unit represented by this packet. The granularity of the time stamp and its exact semantics is type-specific. For example, for audio data types, this time stamp essentially identifies the sample number of the first audio sample contained in the packet. For video data types, however, the time stamp represents the acquisition time of the video frame and is sampled from a 90-kHz clock.
- *Marker bit*: The semantics of this 1-bit field is also media-type-specific. For audio data types, the recommended use of the marker bit is to indicate talkspurt boundaries. For video data types, the recommended use of the marker bit is to indicate the last of a sequence of packets that all contribute to the same media data unit.
- *Synchronization source identifier (SSRC)*: This 32-bit field is used to globally identify the participant associated with this media stream. By using the same SSRC for all RTP streams associated with this participant, the application can associate related streams, such as which video stream belongs to which audio stream.

RTCP is used to provide feedback on the quality of a received media stream and to distribute timing information that can be used to synchronize media streams from different participants and make jitter buffer adjustments. RTCP also supports distributing identifying information associated with a SSRC such as a human-readable canonical name, e-mail address, geographic location, etc. Finally, RTCP can be extended in application-specific ways to provide other types of control information such as floor control, capability negotiation, and other session-control mechanisms. The RTCP specification provides recommendations and algorithms for determining the frequency of RTCP report packets by monitoring the rate of received RTCP packets from other participants. This decentralized approach was motivated by the characteristics of the IP multicast service model, in which the exact number of participants in a multicast group may not be exactly known.

VIDEO REPRESENTATIONS

To some degree, the choice of video compression algorithm to be used within a videoconferencing system is somewhat arbitrary. While keeping bandwidth requirements as small as possible motivates compression, any number of video representations will do. At the same time, however, the computational costs and compression benefits of various compression techniques make some video representations better for videoconferencing than others. In this section, we first describe several general video compression techniques and discuss their suitability for video conferencing applications. Then we quickly review a number of specific video compression standards that were either specifically designed for videoconferencing or have been found to be useful for videoconferencing.

General Video Compression Techniques

At the heart of almost every video compression algorithm is some sort of transform-based encoding that converts the spatial-domain representation of a block of pixels into an equivalent frequency-domain representation of those pixels. The most widely used transform is the discrete cosine transform (DCT). The primary benefits of using a frequency transform is to concentrate the energy of the pixel information into a small number of coefficients. A second benefit is that different coefficients that correspond to different frequency bands can be quantized separately in order to selectively preserve more information in coefficients representing lower frequencies and possibly eliminate coefficients that represent higher frequencies. Although doing so necessitates a loss of information, the human visual system is less sensitive to the loss of high-frequency information. The DCT is particularly useful, since very efficient implementations of the 8×8 2D DCT have been developed.

Motion compensation is another key technique used by most video compression algorithms. Motion compensation exploits the temporal coherence between video frames. Block-based motion compensation tiles the pixel data into non-overlapping blocks of the same size and searches for a motion vector that selects a region of pixels within some reference frame to use a predictive basis for the pixels to be encoded. The residual error values are calculated as the difference between the target pixel values to be encoded and the reference region selected.

The motion vector and an encoding of the residual values are then sent instead of the original pixel values.

Although motion compensation is effective, it creates an encoding dependency between a frame and the reference frame(s) from which the predictive pixel values are selected. This becomes problematic if a frame that serves as a reference frame is lost or contains errors due to packet loss. The use of motion compensation will propagate this error to future frames or even prevent future frames from being decoded at all. In some video compression algorithms, most notably the various MPEG standards, frames are classified by their use of motion compensation. I-frames use no motion compensation at all, and thus in the event of a catastrophic loss of packets, decoding can always be resumed at the next I-frame. P-frames use the previous I- or P-frame as a reference frame. A sequence of P-frames forms a dependency chain, which, if broken or damaged, will propagate errors until an I-frame is encountered. B-frames can use both the previous I- or P-frame as well as the next I- or P-frame as possible reference frames. Since B-frames are not used as a reference frame by any other frame, errors are not propagated. Because B-frames may depend on future frames, however, the encoding and decoding order of the frames is not the same as the display order of the frames. For videoconferencing application in which end-to-end latency is key, B-frames are almost never used because they require additional coding latency in order to encode the future reference frame first. Instead, a sequence of P-frames between periodic I-frames in order to provide error control is most common. Figure 3 illustrates these concepts.

Furthermore, the search for the best motion vector can be very expensive if a large window of motion is considered. Again, this is problematic for a videoconferencing application, in which latency must be kept to a minimum. Fortunately, the video characteristics within a conferencing application lend itself to a number of heuristics. Since the camera rarely moves in a videoconferencing application, global motion due to camera movement is generally absent. Usually pixels are either part of the background or part of a coherent foreground (i.e., the face and body of the participant). Finally, participant motion is generally smooth and reasonably small, so the search for a good motion vector can be abbreviated to a smaller window.

Figure 3: I-, P-, and B-frame relationships

Video Compression Standards

One of the earliest video compression standards specifically designed to support videoconferencing applications was the ITU standard H.261, also sometimes referred to as p*64kbs (ITU 1993). First published in 1990, this standard contains support for two different frame sizes: CIF (352 pixels wide by 288 pixels high) and QCIF (176 pixels wide by 144 pixels high). Pixel data are organized into three planes, with one luminance plane and two subsampled chrominance planes. The standard uses DCT-based transform encoding and forward-only motion compensation. This standard was designed to support videoconferencing over integrated services digital network (ISDN) lines. A variant of H.261, called “intra-H.261,” was developed as part of the early vic/vat suite. In this variant, the use of motion compensation is reduced strictly to either reusing the same block of pixels from the prior frame (i.e., a zero motion vector) or replacing the block entirely with a transform-encoded block of pixels (i.e., not using motion compensation at all).

Experience from the development and use of H.261 led to the evolutionary development of H.263 in 1995 (ITU 2005, H.263). The main improvements included a much wider set of supported frame sizes, the use of arithmetic coding as a final entropy encoding step, wider options on motion vector search, and half-pixel resolution for its motion compensation algorithm. Further improvements were published in 1997 as a series of annexes to the original H.263 algorithm resulting in what is known as H.263v2 or H.263+. The most significant of these was the ability to signal which of several previously transmitted frames was to be used as a reference frame. This scheme, known as NEWPRED, allowed the encoder to use only frames that were known via feedback from the receiver to be properly received as reference frames for future frames. While some temporal coherence is forfeited, the scheme prevents errors in reference streams from being propagated to future frames, thus supporting very long sequences of P-frames.

The most recent video compression standard to emerge for video conferencing is H.264 (ITU 2005, H.264). This standard was developed jointly by the ITU and the MPEG consortium and is also published under the name MPEG-4/Part 10. The standard is also known as the advanced video coding (AVC) standard. This standard was published in 2003 and is the culmination of years of experience and research from both the prior H.26x standards as well as the MPEG-1 and MPEG-2 standards. It has been shown to be capable of providing excellent video quality at a very wide range of bit rates. As a result, many industry experts believe that H.264 will quickly become the industry standard for most video applications including streaming and conferencing. The standard is incredibly feature-rich, and different feature sets are specified in a profile and level system in order to allow different levels of interoperability and to trim the feature set to only those appropriate for a particular application domain. For videoconferencing, the baseline profile (BP) is most appropriate. This profile

includes support for forward (but not backward) motion compensation, multiple reference frames, a deblocking filter, context-based arithmetic coding, and redundant slices, which is a form of forward error correction.

AUDIO REPRESENTATIONS

The data rates associated with audio streams are generally much smaller than the associated video data rates. Similarly, audio encoding is computationally less complex than video compression. This section briefly describes several different audio standards defined by the ITU that have been used in various videoconferencing systems over the years. Since the techniques of representing and transmitting audio in a videoconferencing system are almost identical to those used in VoIP applications, our treatment here is very brief.

G.711

The G.711 standard is an 8-bit-per-sample pulse code modulation (PCM) scheme that uses a simple type of compression called “companding,” which provides approximately the same quality as an uncompressed signal using 12 or 16 bits per sample. This standard was originally published in 1972 for use in telephony (ITU 1988, G.711). The basic idea behind companding is to use a logarithmic scale instead of a linear scale to provide greater resolution for sample values with relatively small amplitudes compared to sample values with relatively large amplitudes. Two main algorithms are defined in the standard, and these variants are commonly called mu-law and A-law. Both variants work in approximately the same way, but the coefficients and constants used by A-law have been specifically selected in order to be numerically easier to manipulate with a computer using binary arithmetic.

G.722

The G.722 standard uses an adaptive differential pulse code modulation (ADPCM) scheme in which the difference between successive samples is encoded instead of the sample values themselves (ITU 1988, G.722). The scheme is adaptive in that the granularity with which these differences are represented is changed depending on the relative size of recent differences. The target bit rate of G.722 is 32 to 64 kbps. Variants of G.722 intended to support even lower bitrates include G.722.1 and G.722.2. All of these variants sample data at 16 kHz, which is about twice that of the standard telephone rate.

G.728

The G.728 standard is a speech-specific codec that uses low delay code excited linear prediction, or LD-CELP (ITU 1992). This method is an example of a vocoder, which attempts to model speech as an underlying fundamental frequency and as set of filter coefficients that modify it. The main feature of the G.728 standard is that it incurs a very small encoding delay and operates at 16 kbps.

THE FUTURE OF VIDEOCONFERENCING

Gaze Awareness

The most recent advances in videoconferencing have been in the direction of increasing the sense of presence experienced by the participants. One way to do so is to provide participants with gaze awareness and eye contact. A common shortcoming of many videoconferencing systems is that because participants are looking at the screen in order to see the other participants and not looking directly at the camera, each participant appears to be looking away at something off to the side or in the distance. Since this occurs for all participants, no one appears to be looking at each other, even though they are clearly talking directly with each other. In multi-party systems, this effect can be particularly noticeable, since gaze awareness (i.e., whom each participant is looking at) is the basis for how people naturally negotiate floor control in a group conversation. One way to incorporate gaze awareness and eye contact into a videoconferencing system is to warp the video image to make it appear as if participants are looking directly at each other (Wa et al. 2003; Gemmell and Zhu 2002; Grayson and Monk 2003). This may require calculating (or at least approximating) the geometric relationship between the camera, the screen, and the participant. Another way to achieve this effect in a meeting room setting is to use pinhole cameras set into a projection screen. In this case, the effect of eye contact is achieved directly.

Another approach to increasing the sense of presence in a multi-party conference is to create a virtual meeting room by combining the video streams of many participants together as if each participant was in the same room. Such a system presents each with a rendering of the virtual space from an appropriate viewpoint. The experimental Coliseum system developed by Hewlett-Packard is an excellent example of this kind of system (Baker et al. 2005). Coliseum used several cameras to capture each participant from several different angles simultaneously. Using these video streams, the system was able to do background separation and calculate a visual hull as a rough approximation of each participant's head and shoulders. This rough geometric information was used to warp the foreground image into a virtual meeting space and render views of this virtual meeting space for each participant.

Tele-Immersion

Whereas Coliseum takes a 2.5-dimensional approach to providing a sense of presence, other research efforts are investigating true 3-dimensional approaches. These systems are often referred to as tele-immersion systems (Kauff and Schreer 2002; Gross et al. 2003; Sadagic et al. 2001). A tele-immersion system captures the imagery of a relatively small (i.e., room-sized) environment from a number of different cameras placed at different viewpoints. These systems may then extract per-pixel information from the video streams using algorithms developed for computer vision. Alternatively, the video streams may be used to form an approximation

of the plenoptic function. The plenoptic function models all of the light rays passing through a volume. Several representations of the plenoptic function have been developed, including light fields (Levoy and Hanrahan 1996), layered depth images (Shade et al. 1998), and concentric mosaics (Shum and He 1999). These systems may also make use of polygonal geometric models derived either from the imagery itself or provided a priori for known structures within the room (e.g., walls, furniture, etc.). At the remote site, all of this information is then recombined into a three-dimensional rendering of the environment. This may be accomplished with head-mounted stereo displays, autostereoscopic displays, stereo project displays, or display caves.

The computational demands and bandwidth requirements of tele-immersion systems are obviously much greater than traditional, single-camera videoconferencing. Although one can easily realize a simple videoconferencing application with commodity off-the-shelf components, a tele-immersion system once again requires complex experimental software, hardware, and networking components. It may be reasonable to ask whether the failure of videoconferencing to live up to its potential foretells a similar fate for tele-immersion. In fact, it is the relative failure of videoconferencing as an application that motivates much of the work in tele-immersion. The argument put forth by many tele-immersion researchers is that videoconferencing does not provide a sufficient marginal advantage over simple audio conferencing to warrant its use. If the sense of presence achieved by a tele-immersion system was compelling to the point of people truly feeling that they were within a shared space, the marginal utility of using such a system would increase. Furthermore, tele-immersion systems would then find use in situations that demand such a compelling sense of presence such as battleground operations or surgical procedures.

GLOSSARY

Application-Level Framing (ALF): A design principle that argues that hidden costs and limitations of the network should be exposed to the application in order to best adjust the packetization and framing of application data units.

Application-Level Multicast (ALM): An implementation of multicast that does not rely on in-network support for packet replication and forwarding but organizes the participants of the multicast group themselves into a peer-to-peer distribution tree.

Arithmetic Coding: A form of lossless entropy encoding that produces near-optimal compression given a specific model of symbol frequencies.

B-Frame: A video frame that uses motion compensation using reference frames from either the near past and/or the near future but does not serve as a reference frame itself.

Churn: A term used to characterize the dynamics of multicast or peer-to-peer group membership.

Content Distribution Network (CDN): An overlay network embedded within the Internet using provisioned resources carefully located at strategic peering points.

- Discrete Cosine Transform (DCT):** A transform coding technique that represents a one- or two-dimensional field of pixel values in the frequency domain using cosine functions that form an orthonormal basis.
- Elasticity:** The degree to which a media type can be displayed at rates that deviate from the original sampling rate with little observable decrease in quality.
- Entropy Coding:** A data-compression technique in which variable-length codes are assigned to input symbols in order to take advantage of an uneven distribution of symbol frequencies.
- E-Policy:** One end of the spectrum of jitter buffer policies in which the playout delay is adjusted to accommodate the largest observed delay.
- Exponential Weighted Moving Average (EWMA):** A technique for estimating a long-term average from spot sample values of a noisy signal in which the contribution of a spot value decays over time.
- Floor Control:** A mechanism for determining which participant in a conference is the primary speaker at any given time.
- Forward Error Correction:** A technique for proactively sending redundant representations of previously transmitted information in order to guard against possible packet loss.
- Gaze Awareness:** The ability (either simulated or real) for a conferencing participant to establish eye contact with another participant.
- I-Frame:** A video frame that is encoded without use of motion compensation such that it can be decoded correctly whether or not previous frames have been received or contain errors.
- IP Multicast:** An in-network forwarding service that allows a packet to be sent to a group of receivers by replicating the packet at routers in order to traverse a distribution tree.
- I-Policy:** One end of the spectrum of jitter buffer policies in which the jitter buffer is never adjusted after a playout delay has been established, despite future variations in delay.
- Jitter:** The variance of transmission latency experienced in a packet network.
- Jitter Buffer:** A receiver-side mechanism for ameliorating the effects of jitter.
- Motion Compensation:** A video-compression technique that uses past (or possibly future) frames to predict the value of blocks of pixels by discovering global or local motion within the scene and transmitting only the residual difference.
- Multipoint Control Unit (MCU):** A component of a centralized conferencing architecture that is responsible for receiving the media streams of each participant and transmitting a composite stream back to each participant for display.
- P-Frame:** A video frame that uses forward-only motion compensation from a past reference frame and may serve as a reference frame for other frames.
- Peer-to-Peer (P2P):** A decentralized application architecture in which peers participate with equivalent or similar capacity and communicate directly with each other.
- Playout Delay:** The end-to-end delay target used to schedule the display of a media unit.
- Plenoptic Function:** A function that models all light passing through a volume in space.
- Real-Time Control Protocol (RTCP):** The IETF-developed control and feedback protocol designed to be used in conjunction with RTP in conferencing and streaming systems.
- Real-Time Protocol (RTP):** An IETF-developed transport protocol based on the principles of application-level framing used in videoconferencing and streaming systems.
- Single-Source Multicast:** An alternative to IP multicast that limits each multicast group to have exactly one prespecified source of packets.
- Stress:** A metric used to evaluate how often a duplicate packet traverses any given link using an application-level multicast scheme.
- Stretch:** A metric used to evaluate the latency penalty of the path from source to receiver in an application-level multicast scheme as compared to the shortest unicast path available.
- Talkspurt:** A period of audio samples that correspond to continuous speech separated from the next and previous talkspurts by silence associated with natural breath pauses and/or changes in who is speaking.
- Tele-Immersion:** An advanced form of videoconferencing in which three-dimensional information and multiple camera angles are used to provide a heightened sense of presence.
- Vocoder:** An audio-compression technique designed for human speech that analyzes an input signal in order to derive coefficients and parameters for a corresponding synthesis process.

INTRODUCTION

The history of communications is filled with examples of a nearly insatiable demand for connectedness. As dispersed work has become more common practice among business and public institutions, so too has the need for computer-facilitated solutions that enable efficient work collaboration among those separated by distance or responsibilities within business enterprise functions.

Computer conferencing systems are an evolving family of information communication technologies supported through a variety of protocols, which can be selected depending on the communication functions desired by those involved in the conferencing application (Table 1). For example, network voice protocols (NVPs) can enable computer conferencing functions as simple as a telephone

conference that is scheduled and monitored by a computer. When conferencing communication requires rapid online text interchange, Internet relay chat (H.323 IRC) can provide the needed functionality. A growing number of computer conferencing applications are optimized with voice over Internet protocols (VoIPs) combined with an interactive Web site where multiple users manipulate documents through a common database, share screens and talk with the group, instant message, or a combination of these. Real-time transport protocols (RTPs) enable opportunities for more complex communications by adding multimedia communication connecting supporting digital interaction among multiple users. Increasingly, computer conference participants are beginning to add Web cams into the mix, effectively blurring the lines between a computer conference

Table 1: Computer Conferencing Protocols

VoIP (voice over Internet protocol)	VoIP routes voice conversations over the Internet over an IP-based network using a packet switched network rather than telephone lines.
H.323, IRC (Internet relay chat [IRC])	IRC is a plaintext, open protocol used for instant communication over the Internet. Users initiate the protocol by connecting a client to an IRC server.
RTP (real-time transport protocol)	RTP is a standardized packet format for delivering audio and video data over the Internet using a dynamic port range.
SIP (session initiation protocol)	SIP is a protocol designed for initiating, modifying, and ending user sessions using interactive media such as online games, video, voice, instant messaging, and virtual reality.
NVP (network voice protocol)	NVP is an early protocol for transporting voice communications over the Internet via packets. It can be viewed as a precursor to VoIP.

and a videoconference. These are just several examples of common protocols that facilitate today's computer conferencing applications.

Although evolving protocols enable increasingly rich interactions, the more basic computer conferencing technologies have been available for many years. Both real-time and asynchronous text communication, in fact, have been around since the very earliest days of the Web and continue to play a role in computer conferencing today. First-generation online technologies such as e-mail, listservs, and bulletin boards were a valuable step forward for collaborative computing; however, the functionality of these early technologies lacked the complexity needed for many distributed team collaboration applications. For example, e-mail is optimized for one-on-one communication and listservs and bulletin boards lack the dynamic and targeted communication functions often desired for teamwork.

NetMeeting was the first true Web conferencing application that allowed screen sharing, file sharing, and real-time communication and a much richer experience than a simple text discussion. NetMeeting was introduced by Microsoft in the mid-1990s as a free download that relied on peer-to-peer communication to function. Since then, many vendors—such as IBM, Cisco, WebX, GoToMeeting, and Genesys—have entered the market.

New generations of computer conferencing tools are designed to meet the need of enhanced integrated communication that provides a rich collaborative work environment for participants working from multiple locations and with potentially very different communication needs and abilities. Evolving open standards based on Internet protocols such as session initiation protocol (SIP) are rapidly enabling more complex and rich integrated computer conferencing flexibility than early generations of software. Today's Web conferencing tools typically include things such as text conferencing and videoconferencing capabilities, shared calendars, discussion forums, document sharing, instant messaging, and whiteboard features, either offered individually or in combination. They allow for both real-time and asynchronous communication.

Under optimal circumstances, computer conferencing and Web collaboration tools are both easy to use and rich enough in functionality to support more complex integrated voice, video, and data communication interactions. Unfortunately, the reality is that there is generally a trade-off between ease of use and the degree of communication functionality that can be supported by computer conferencing software. Conferencing software that can support complex integrated communication functions often can be difficult to use, and especially complicated to maintain and integrate, with users operating from multiple platforms and with diverse experience. It is not probable that online collaboration can ever fully replace face-to-face communication. Nevertheless, the future is a promising one, in which computer conferencing software continues to make inroads into supporting complex business and social communication needs.

This chapter explores the origins of computer conferencing, its value in application, as well as emerging protocols important to the future of conferencing and collaboration in the digital world.

THE PARADIGM SHIFT TO COLLABORATIVE COMPUTING

Computer conferencing and Web collaboration are a mainstay of human interaction within today's workplace; however, they are relatively recent within the history of computation. Indeed, computing began as a solitary task. From the inception in 1940s until the late 1960s, the fledgling computational machines filled entire rooms and were accessible by only one user and one program at a time. Tracing the history of collaborative computing, Laiserein (2000) notes it was not until the introduction of AT&T Bell Lab's UNIX platform in 1969 that a paradigm shift emerged with an engineering transformation to support the sharing of simple files for real-time collaboration among multiple users. David Wooley (1994) identifies the origins of computer conferencing to have occurred as early as 1973 with the creation of PLATO, which was among the early systems to pioneer online forums and message boards, e-mail, chat rooms, instant messaging, remote screen sharing, and multiplayer games, leading to the emergence of what was perhaps the world's first online community.

In the 1960s and 1970s, most computing was accomplished with large mainframe computers shared by multiple users. However, the mainframe computing environment at that time was still relatively inaccessible and available to only an elite few in universities and large research organizations. Consequently, although collaborative computing was technically enabled in the early 1970s, the number of people with equipment and knowledge to engage in such collaboration was relatively small.

DEC delivered its first production version of the PDP-1 microcomputer early in 1961. In his detailed history of personal computing technology, Alan (2001) observes that the term *personal computer* was coined to make a distinction from the shared mainframe devices to recognize a computer made for use by one individual. Although the personal computer (PC) began to gather greater commercial significance and became more affordable to ordinary people later in the 1970s, the technology was not an immediate catalyst for collaborative computing. Rather, PCs were used as smaller personal versions of the early mainframe devices, with single users accessing stored files from their personal digital storage space at a given time. In the 1980s, the practice of computing as an independent solitary task was eventually overtaken by a growing value being found in the early UNIX-based Internet, which was transformed to be accessible to PC users. However, it was not until the following decade and the acceptance of Tim Berners-Lee's World Wide Web as the system of standards that would enable computer owners throughout the world to share and exchange information in a common format that the paradigm of collaborative computing began to truly accelerate (Berners-Lee and Fischetti 2000).

EMERGENCE OF VALUE: A NEW GENERATION OF INTERACTIVE DIGITAL NETWORKS

Ultimately, the value of computer conferencing hinges critically on the availability of a robust and cost-effective

digital communications network over which conferencing applications can be conducted. George Gilder (1993) coined the phrase *Metcalf's law*, recognizing the groundbreaking work of Robert Metcalf in creating a formula to predict the value of communication network technologies. Specifically, the value of a network equals the square of the number of users, while the value of an individual is proportional only to the number of users.

Prior to 1990, the value of computer conferencing was limited in part because an accessible interconnected network did not exist. With the Internet and eventually the World Wide Web well established to support the interconnectivity needs of the growing number of businesses, public institutions, and households owning PCs, the necessary foundation for the takeoff of computer conferencing and associated Web collaboration tools was in place by the early 1990s. Businesses, public institutions, and to a lesser extent, ordinary households became aware of the power and value of being able to communicate and share data with others around the world using connections through the Internet.

Along with the recognition of value came new consumer demands for both software and hardware to improve the versatility, functionality, accessibility, and affordability of computer conferencing and collaboration. Not only was there a growing demand for digital tools, enabling the productive sharing of data, voice conversations, and video images, but also there was a growing demand for real-time access to desired digital information 24 hours a day, 7 days a week using multiple information communication devices from a variety of locations.

With expanded recognition of the potential value of modern computation as an "always-on" information communication network, computer equipment and software engineers moved into high gear in the 1990s. Initially, new products and services catered to the business customer who wanted to communicate, real-time and anytime, with customers and business partners around the globe using a full suite of integrated digital data conferencing, voice conferencing, and videoconferencing capabilities. The rapidly growing suite of digital computer conferencing tools, designed first for global business purposes, very quickly evolved to meet the needs of small businesses, schools, health care organizations, and individuals.

As advances and affordability of microchip technologies continued, various innovative computer conferencing technologies quickly came to market, including videoconferencing shared digital workspaces for project collaboration, instant text messaging, asynchronous text conferencing, enterprise information portals, real-time digital whiteboards, shared data storage applications, and others. This, along with a variety of Web-application service providers that were available to help business and individual customers use and cost-effectively integrate and apply the growing suite of computer conferencing tools, provided customized solutions to individual challenges.

Further catalyzing the demand for computer conferencing products and services was the concurrent expansion of mobile computing and communication technologies, beginning with mobile phones and morphing quickly into new personal digital devices with the computing power of desktop PCs only a few years earlier. Historical

telecommunications data published by CellularOnline (2006) indicate that in 1992, there were only about 200,000 handheld mobile phone units in use worldwide. By 2004, there were well over 1.5 billion handheld mobile phones in use throughout the world. In addition to these handheld devices, ownership and use of powerful laptop computers has skyrocketed over the past decade, further enabling computer conferencing and digital work collaboration to be possible almost anywhere an Internet connection is feasible.

Another critical technological enabler catalyzing the value of computer conferencing is the wider availability of high-speed Internet connection points. Broadband wireless technologies continue to proliferate both within and outside of the United States, making 24/7 high-speed Internet connections for computer conferencing available not only at the usual place of work, but also in airports, hotels, coffeehouses, and other locations where computer users may gather.

A final and important network enabler of computer conferencing is the growing universal availability of free or low-cost voice over Internet protocol (VoIP). VoIP can be expected to have a transformative impact on computer conferencing capability by providing a critical link of fully compatible video, data, and voice connections to be cost-effectively integrated over a single Internet communications backbone.

TECHNOLOGY EVOLUTION

Although Web-based communication tools have been with us for a number of years, there has been a recent shift in their design that changes the way people can work together over the Internet. Table 2 illustrates the transformation from first-generation Web tools to new tools that allow a different attitude about collaborative work. In each instance, there is a change from a hierarchical management system controlled by a select group of people to fully collaborative and personalized creative work spaces.

Online tools have evolved over the past several years to improve the perceived value of computer conferencing for collaborating colleagues. Taxonomies and BitTorrent, for example, allow participants working from diverse contexts, to more easily customize conferencing applications to their unique scenarios. Wikis and blogging enable content development from multiple participants without hierarchical filters to more closely match the way work is actually accomplished in many organizational settings. Web services enable more effective collaboration among participants working from different organizations or remotely in different time zones to effectively participate in conferencing. These are just several of the positive recent trends improving the relevance and the likely acceptance of computer conferencing within the business setting.

THE TRANSFORMATION OF WORKPLACE

Computer conferencing has significantly changed the business paradigm and the way work is accomplished in much of the industrialized world. Francis Cairncross

Table 2: Evolution of Collaborative Online Tools

First-Generation Closed Systems for Managing Internet-Based Tools	Second-Generation Open Systems for Facilitating Internet-Based Work
Directories: Content organized by database developer trying to second guess keywords that users will need.	Taxonomies: Users post their own content to the database and write keywords themselves.
Akamai: Content caching for large files such as applications or videos that are downloaded via http.	BitTorrent: Content caching and file sharing via a peer-to-peer swarm that can handle much larger files than Akamai can.
Top-down content management: Content is given to a select individual (or small group) who then edits, organizes, and publishes approved content.	Content management through wikis: All participants organize and publish directly to the Web site.
Screen scraping: Content-capturing technique involving crawling and capturing data not intended for sharing beyond its original publication.	Web services: A more sophisticated content-capturing technique that supports a decentralized machine-to-machine interaction over a network.
Single-source publishing: A Web site published by an individual at a single URL.	Mash-ups: Content as well as layout are gathered from multiple Web sites and reassembled into something new.
Personal Web sites: Single-source publishing that can be viewed through a Web browser. The site designer controls how viewers see the information.	Blogs: Allow interactivity through comments. Allow users to customize their experience through sorting, filtering, saving individual posts, and managing posts through RSS readers.
Streaming Web seminars: Individuals follow along as they listen to others speak.	Collaborative online tools: Individuals can interact with the speaker, comment, share files, and talk with other participants.

(1995) writing for *The Economist*, characterized the social and economic impact of the new generation of digital networks combined with emerging computer conferencing applications with the coining of the phrase “The Death of Distance.” In today’s accessible and affordable digital collaboration, geographic proximity to customers, suppliers, markets, and business partners is much less critical than in the days prior to accessible and affordable computer conferencing.

Nicholas Economides (2004) has traced the evolution of the pricing structure of digital information and communication channels. Prior to the development and rapid adoption of the World Wide Web, the cost of communicating internationally or between cities increased with distance. However, with a growing array of competitive communication options, including VoIP, both voice and data communication costs very little extra today to communicate over long distances than over short ones. Consequently, the historical advantage of being located close to customers, suppliers, or even a specific workforce is much less relevant today than was the case prior to broad availability and acceptance of computer conferencing.

Concurrent with the advances in favorable economics for dispersed work has been a steady shift of workforce functions away from manual occupations to occupations that focus on the creation and processing of knowledge. Using federal census data from 1950 to 2000, Wolff (2005) found that the proportion of the U.S. workforce engaged primarily in “information work” increased from 37 percent of the work force in 1950 to 59 percent in 2000.

Sophisticated computer conferencing tools translate into new opportunities for business and professional people all over the world. Because many tasks can now be

accomplished over the Internet, businesses can hire workers anywhere there is adequate communications connectivity. The result is savings on wages and real estate costs as well as opportunities to recruit the best talent any place in the world without need for relocation. If a company’s best talent is no longer concentrated in a single city or even a single building, disruption in services due to natural disasters is no longer an issue. Employees distributed geographically can carry on with business as usual despite any disruptive event in a particular geographic location.

Because many computer conferencing systems allow a great deal of collaboration and real-time interaction, companies can enjoy savings by eliminating the need to squander time and money on endless travel for meetings. Talented peers can work together across thousands of miles and many time zones. In some instances, workers across the world can collaborate in a way that keeps project development moving around the clock.

THE NEXT FRONTIER: PEOPLE

The dot-com financial boom of the 1990s—driven in part by the perceived productivity gains that could be obtained through computer conferencing and collaboration—took a tumble in the early years of the new millennium. A number of factors contributed to the bursting of the dot-com bubble, one of which was that technological advances proceeded at a pace ahead of people’s ability to effectively manage and use the emerging information and communication technologies.

In an analysis of collaborative computing practices within 41 large businesses, Brynjolfsson (2005) documents that many corporate executives were forced to

come to terms with the reality that technology investments of the 1990s were not producing the expected productivity gains. Innovation in the application of information technology to business processes proved insufficient to realize the full potential for productivity gain. The perceived value of computer conferencing equipment and services enabled by a new generation of digital networks deflated as meaningful business evaluations were brought to the boardroom. The lesson to be learned is that companies and public institutions must make complementary organizational investments in addition to IT investments to fully take advantage of the power of computer conferencing.

As a result of these lessons learned, today multidisciplinary teams are more likely to join with engineers in the design of future generations of computer conferencing and online collaboration tools. For example, leading companies within the software and microprocessor industry have hired and expanded teams of ethnographers to join with product development teams. "Social computing" is recognized for its important commercial value within corporate research divisions as well as in major research universities. Consequently, a comprehensive survey of the current state of computer conferencing protocols and applications would be incomplete without careful consideration of the emerging challenges of understanding how people desire to relate to and use their technology, and how business processes must be reshaped to fully take advantage of productivity gains that can be achieved through computer conferencing.

WORKPLACE IMPLEMENTATION CHALLENGES

As the reliance on information and communications technology for workplace interactions has expanded, so too have the challenges of meeting the needs of people who are required to use those technologies. Galinsky et. al. (2004) document in a study by the Families and Work Institute that 56 percent of North American workers say they typically have to work on too many tasks simultaneously or are interrupted in the work day so many times that they find it difficult to get work done. An in-depth study of 24 information workers by Gonzalez and Harris (2005) reached similar conclusions, with 57 percent reporting frequent work interruptions largely attributed to managing multiple simultaneous task using technological work systems.

In many workplaces, the aggregate number of electronic communications—e-mails, instant messages, calendaring requests, and so forth are rising at a rapid pace. Farhoomand and Drury (2002) found that the two most common sources of information overload were an excessive volume of information (reported by 79 percent of respondents) and difficulty or impossibility of managing it (reported by 62 percent of respondents). A Microsoft white paper (2005) says that information workers spend up to 30 percent of their working day just looking for data they need. When the volume and pace of information becomes so great that it exceeds the ability of people to process and use that information, digital collaboration can undermine rather than enhance worker productivity.

Whatever their skill level, many people develop their own methods for dealing with the expanding volumes of online workplace communication. Some of those methods may be the digital equivalent of duct tape and bailing wire. But however ineffective, they are also familiar, and getting busy people to change habits and learn new skills can be a daunting task. For example, Bellotti et al. (2005) provide detailed surveys documenting task overload and loss of productivity that occurs for knowledge workers as a result of overreliance on e-mail to accomplish collaborative communication, especially as the range of people and topics of communication expand. The implication for employers seeking productivity and efficiency gains from computer conferencing is that no matter how user-friendly or comprehensive the solutions offered by software vendors, organizational systems that create a workplace environment in which people are likely to accept and use those solutions must be in place first.

Computer conferencing tools are designed to enable collaboration among coworkers. But as organizational leadership analysts Thompson and Good (2005) observe, within many organizations, a culture of collaboration is dangerously lacking, and many workers are challenged with digital collaboration scenarios that are largely new and unfamiliar. Today it is uncommon for workers to know, share common space with, and work the same hours or even for the same organization as all the people with whom they collaborate. This, of course, is the precise scenario in which computer conferencing tools can potentially add the greatest benefit. But in the end, it is the motivation, skills, and comfort level of people using those tools that makes collaboration in a modern heterogeneous, dispersed, asynchronous work environment possible.

The motivation, skills, and comfort levels in using the tools of digital collaboration are in no small measure linked to the organization's management culture. A study by MIT's Center for eBusiness concluded that organizational culture was a defining factor among corporations most successful in achieving desired productivity gains from investments in collaborative computational technologies (Brynjolfsson 2005). Notable computer conferencing tools are most applicable to organizations that instill and practice core values that include open communication, decentralized decision authority, and teamwork. The technology tools themselves cannot produce the intended benefits of collaboration. However, well-designed computer conferencing tools can enable organizations to be successful when those organizations have made a commitment to practices that empower dispersed decision-making authority and human organizational processes consistent with effective virtual team collaboration.

Organizations seeking to reinvent themselves with a commitment to open information sharing and dispersed decision making are often quickly faced with the need to deal with additional challenges of information overload. If not addressed, this becomes a new fatal flaw beyond that which can be addressed through technology design alone. In his cross-industry research on collaborative computing use, Brynjolfsson (2005) found that the most successful organizations deal with these competing goals through support, training, and merit reward systems that help workers make good choices both with respect to

specific technology tools to use in specific situations and rules of engagement for the efficient sharing of information among collaborative teams. He notes Cisco as an example of a company that has been successful by instituting a comprehensive workforce development process that uses merit rewards to encourage virtual team collaboration and intranet “dashboards” that help employees access the information most relevant to their jobs.

Nardi (1996) provides a comprehensive analysis of ethnological and anthropological research to demonstrate the inseparable connection between the human context of communication needs and successful application of computer and Web tools in the workplace. For information professionals responsible for the design and ultimate adoption of computer conferencing and work collaboration systems, the implications are clear. A holistic systems approach that empowers the organization with a culture of collaboration, technology support and training appropriate for busy people, and a refocusing of management skills to meet needs of dispersed teams are all required to achieve the hoped-for productivity gains promised by computer conferencing.

CONFERENCING TECHNOLOGY SYSTEMS DESIGN WITH PEOPLE IN MIND

Genevieve Bell, an anthropologist, was charged by Intel to travel throughout Asia and observe how people from different cultures choose to use computers and computer devices. Oanh Ha (2004) notes some of Bell’s surprising observations, including Muslims using global positioning system technology to find Mecca at prayer time, elderly Indian grannies using text messaging to keep in contact with relatives around the world, and cell phones being blessed at temples because they are such an integral part of people’s lives and identities.

Bell is one of a growing number of anthropologists trained in ethnographic methods hired today by both hardware and software design companies. This is because it is widely recognized that information technology managers within organizations, as well as those who design the digital tools, need to begin with an understanding of how people desire to use those technologies. Within the domain of computer conferencing, this basic principle is of even greater importance because the systems must be designed to accommodate collaborating participants, often with very diverse levels of technology skills, experience, motivation, time demands, and cultural perspectives.

Collaboration tools that are not broadly accessible and able to be used by all members of the group for which collaboration is desired will ultimately be counterproductive. In practice, the concept of accessibility is complex, with multiple facets, but they can be grouped into two broad categories of consideration: (1) participants must have the ability to access and the ability to use required computer conferencing software and (2) participants must have the motivation, skills, and knowledge required to use the available conferencing and collaboration tools.

These two broad sets of issues are important considerations for both those who create computer conferencing

software and those responsible for the design of systems to optimize the use of available computer conferencing tools within organizations. Because of the diversity of needs, skills, and experience of potential computer conferencing participants, system designs must be able to flexibly accommodate diverse circumstances without adding unnecessary complexity. Examples of critical design considerations include:

- Degree of interoperability across multiple platforms
- Potential restrictions of lower communication bandwidth
- Data and information security
- Ability to easily integrate into group work habits
- Simplicity of use and training requirements
- Universal design accommodating persons with disabilities

The workplace communication tools required by today’s information workers must continue to evolve to meet new needs and provide new capabilities. For example, information workers today are much more likely to be required to collaborate with colleagues from other organizations and with a broader set of business enterprises within their own organizations. With continued economic globalization, computer conferencing increasingly must accommodate persons collaborating from multiple time zones and differing standards of underlying telecommunications. Business analyst I.M. Weinstein (2005) observes that broadening collaboration is a trend among information workers to rely on multiple communication devices operable from multiple locations. Today’s workers are often highly mobile, using a combination of office desktop computers, notebook computers, handheld devices, and desktop computers from remote locations in accomplishing their work.

Consequently, designers of computer conferencing solutions are faced with the challenge of creating solutions that work across multiple platforms and with equipment supported by highly variable underlying communication capabilities. As a result, there is a much higher premium on computer conferencing capabilities that are interoperable across multiple platforms without unacceptable loss of key functionality when the underlying digital communication bandwidth is limited.

Yamauchi and his colleagues (2000) document a growing trend toward open source computer conferencing solutions as a potential avenue for organizations to address the pressing need for greater interoperability allowing work teams to customize work collaboration tools to meet needs and provide cost-effective access to those tools to participants from multiple organizations. However, open source solutions may also come with the additional challenge of requiring members of the work team to have code-writing expertise to customize software tools with adequate functionality to meet specific workforce needs.

Although the expense of proprietary computer conferencing solutions is a potential barrier to access, they often come with more user-friendly interfaces and customer support, making initial implementation easier. Whether

proprietary or not, the challenge of enabling organizations to flexibly meet the diverse conferencing scenarios typical of today's information work are best met through open XML standards and available development tools that empower users to build and extend applications as needed.

As computer conferencing software developers continue to expand options for open information sharing across platforms, new potential security and privacy threats arise. Information technology (IT) managers who address these threats with stronger corporate firewall protections requiring manual registration and authorization of all participating users may unintentionally erect new barriers to collaboration as employees are unwilling to take the additional time and effort needed to include colleagues from outside the organization, even when policies allow for such inclusion and opportunities invite the collaboration.

The trend toward software developers relying on open XML standards offers opportunities not otherwise possible for corporate IT managers to customize applications to improve security, reliability, and manageability in a manner most consistent with the working style and needs of the organization's information workers. Potential solutions are also found in a new generation of Web services, which make it possible for organizations to share information with partners by creating a common understanding of how data are structured, shared, and secured.

A repeated theme emphasized throughout this chapter is that the success of computer conferencing in addressing desired work collaboration goals hinges critically on technology solutions that are appropriate for the way members of an organization desire to work and that minimize the challenge of participants in using the conferencing software. For a solution to be successful, software designers must provide users with access to basic features such as Web conferencing, shared calendars, discussions, shared workspaces, document sharing, instant messaging, and whiteboards in a format that minimizes training requirements.

Drawing on the ethnological and anthropological research described earlier, it is critical that designers integrate knowledge about the real-world work practices and behaviors of knowledge workers into their design efforts. The most powerful computer conferencing solutions are not necessarily the best solutions. Design solutions that use Web interfaces with a look and functionality familiar to most users of the conferencing software add value by enhancing the probability of widespread use.

The accessibility of computer conferencing software is also enhanced with designs that recognize the need to include populations with disabilities. In the United States, 18.1 percent of people are impacted by a disability compromising their vision, hearing, mobility, or learning. (Steinmetz 2002). This number is projected to rise significantly as the global population ages and the current growth in the incidence of diabetes continues to take its toll. Employment is the most significant challenge facing persons with disabilities.

Stodden and Dowrick (1999) found less than 30 percent of working-age adults with disabilities have even part-time employment. The Internet supported with computer conferencing tools has the potential to serve as an equalizer,

creating opportunities to tap talent, ideas, and contributions from those with disabilities that make it difficult to leave home. Many persons with disabilities, who would not be able to participate fully in a face-to-face meeting because of physical limitations or because of simple prejudice, can fully participate in interactive Web-based events using adaptive technologies. In addition to benefiting from the previously hidden talent of this growing segment of our population, and providing employment opportunities, there is the added opportunity to change attitudes about disabilities among the rest of the population.

None of this is possible, however, unless developers create products that meet basic accessibility standards. With appropriate up-front consideration and planning, it is entirely feasible to accommodate the communication needs of populations with disabilities. Such modifications in design can also result in many secondary benefits for the enabled population as well. This is a basic principle of the universal design concept; it applies broadly to products and environments made usable by anyone regardless of disability. For example, curb cuts that were built to accommodate wheelchairs are much appreciated by parents pushing strollers and people on bicycles. The same is true for Web applications. A site that is fully accessible to a text reader also downloads easily to handheld devices. Images with alternative text tags are welcome to users with slow connections or those who prefer to disable images in their browsers. Accessibility principles applied on the Web make Internet tools more flexible, easily personalized, and usable for everyone.

CONCLUSION AND THE DIRECTION FORWARD

Wellman (2001) notes that computer networks are inherently social networks, linking people, organizations, and knowledge. The value of IT systems must be considered in the context of the lives of people who use those systems.

The ability to personalize our online work experience, collaborate, and co-create with colleagues anywhere in the world continues to improve with each revision of new computer conferencing tools. These tools continue to transform into operational frameworks that are more intuitive, flexible, and inclusive. However, technological innovation as well as organizational systems innovations must continue to evolve before the envisioned benefits for business productivity gains and effective collaborative work can be fully realized.

Research conducted by Benford and his colleagues (2001) documents that most people who collaborate online today do so with a customized collection of tools they assemble to meet their specific needs. Although collaborative computing technology can enable productive and meaningful interactions, ultimately it is human beings who make meaning and connections from the information that is shared. Contemporary Internet tools are limited because they are designed to parse content as raw material for humans to sort out.

Today, computer software programs can organize headings and links, they can sort information according to keywords, and they can provide text boxes for people

to communicate in. However, they cannot prioritize or connect the meaning or semantics of any shared information. It is up to people to make meaning that leads to decisions. Henderson (2005) found that knowledge workers working on the same job and with the same software systems typically have significant variance in their selected hierarchical file structure for storing digital documents. Such variances in the way people choose to organize their personal digital documents can be a substantial barrier to effective work collaboration. The most dramatic future advances in computer conferencing will most likely be in the domain of managing information among workgroups.

The originator of the World Wide Web, Tim Berners-Lee (2001) envisions the emerging Semantic Web as a transformative technology in which information is given well-defined meaning, better enabling computers and people to work in cooperation. To envision the transformative potential of the Semantic Web for productive collaboration, imagine a company that needs to find a php programmer to develop a Web site. Using a variety of online databases available today, it is feasible to quickly develop a list of names and resumes of potential candidates. But the online process ends at this point and a new round of communication through e-mail or telephone must be initiated after reviewing the candidate pool.

With the addition of a Semantic Web agent, the online search process would not end with the passive process of identifying a pool of trustworthy programmer candidates matching the desired skill base. The online process would be enabled to continue beyond the first step of identifying possible employee candidates. For example, the Web-enabled decision process could continue by making an appointment for the assigned company representative to have a VoIP meeting at a time that fits into both persons' calendars. In many cases, the manager conducting the search may desire to consult and obtain views of other colleagues before initiating contact with potential programmers with the desired skill set. The Semantic Web agents of colleagues within the organization would be linked to contribute their perspectives and possibly to volunteer them to participate in the interview meeting as well.

This is just one example of the potential of the Semantic Web to enhance computer conferencing as a tool for meaningful work collaboration. Human interaction is, of course, still required. However, the information will be stored, tagged, and parsed in a way that is easy for machines to communicate with one another and for semantic software agents to discern meaning for the individual requesting the information to adjust and improve the quality of the information based on the human user's interaction with it. Microsoft founder Bill Gates (2005) envisions a near-term business environment in which software will play an important role in replacing the complexity of the workplace with contextual information needed for decisions involving joint interaction among people from multiple organizations working from many different locations.

This vision for the future of computer conferencing is much more than an improved and more powerful tool for the sharing of data and information. It is a vision in which computer conferencing will provide colleagues

in the workplace with the ability to make real-time decisions with comprehensive knowledge of how their work connects with others within the same organization and others with connected work outside the organization. The ultimate benefit of computer conferencing will hinge on success in creating flexible, intelligent software systems that reflect the way colleagues in the workplace desire to interact for decision making rather than requiring people to change the way they must interact to meet the requirements of the conferencing software.

GLOSSARY

Asynchronous Communication: Any method of communication that does not demand real-time responses from participants. Individuals contribute to a dialog at any time and place that is personally convenient. Examples include message boards, e-mail, listservs, and Web-based threaded discussions.

Information Communication Technology (ICT): Any technology that enables the sharing of data, text, images, or voice communication. Computers and cellular telephones both fall within this category.

Open Standards: Nonproprietary and publicly available, allowing anyone with the expertise to implement them. They are designed using an open and collaborative method by teams of experts. Applying open standards ensures compatibility with various hardware, software, and vendors that design with open standards.

Persons with Disabilities: The definition of a disability varies depending on the source. A broad definition includes any physical or mental impairment that significantly interferes with ordinary day-to-day activities such as blindness, a missing limb, or a learning disability. A social definition of *disability* refers to barriers in society in relation to a person's impairment—the idea being that the limits of an impairment are socially imposed.

Semantic Web: A World Wide Web Consortium-sponsored project that seeks to develop intelligent systems for machine-to-machine communication that will self-adapt and refine its processes based on user behavior.

Social Computing: The software that supports the growing trend in ICT for social interaction, collaboration, and communication.

Web Application: A software application tool that is accessible over the Internet through a browser instead of through one's local hard drive.

Whiteboard: Whiteboard software replicates whiteboard writing surfaces commonly used in schools and offices. Electronic whiteboards allow users to draw pictures and write freehand messages that can easily be erased and modified. They are a common feature in collaborative virtual meeting software and instant messaging.

XML: The extensible markup language (XML) is a standard developed by the World Wide Web Consortium (W3C) designed for cross-platform machine-to-machine communication and capable of describing many kinds of data.

TELECOMMUTING AND TELEWORK

As a result of the World Wide Web phenomenon a well-spring of new terminology has made its way into the common vernacular such as *blog* and *mudding*, and many of us have participated online in discussion boards or chat rooms used by *virtual communities*. At one time or another, most of us have been online gathering information or transacting business. Contemporary society is being shaped around the emerging technologically mediated ways of interacting, and there are a growing number of online transactions in which telecommunications are substituted for in-person acquisition or performance of services. Examples include online or distance education, online shopping, online banking, telemedicine, telejustice, teletaxes, televoting, and virtual entertainment (Bureau of Transportation Statistics 1992). And events, such as 9/11, and disasters such as the Northridge earthquake in California, have caused some to wonder if telework might serve as a potential mitigation or disaster recovery option. It is only natural then to expect that new forms of telework would emerge. It is important, however, to distinguish various forms of online transactions (or what might be called “telebusiness” or “e-business”) from telework because telework carries with it a variety of unique characteristics beyond transacting online.

The term *telework* is typically applied to an arrangement in which someone works from a remote location away from a traditional office building or on the go in a mobile environment (Hertel, Konradt, and Orlowski 2004). It began as telecommuting, where someone would work from home on a part-time basis (Nilles et al. 1976). Today, with transnational organizations proliferating along with globalization we are seeing the emergence of new forms of telework, such as virtual teaming, particularly among organizations involved in knowledge work (ITAA 2003). These forms of virtual work enable corporations to transcend geographies and time zones and get closer to customers, suppliers, and trading partners, and more effectively respond to turbulent business environments through their “instantaneity”—anytime, anywhere work (Baruch and Nicholson 1997). In this chapter we examine

some of the forms of virtual work, their relative advantages and disadvantages, and some of the managerial and employee issues and questions that must be addressed. We also look at some of the social, legal, and technological implications and various roles technologies are playing in the emergence of virtual work.

Forms of Virtual Work

In his book *The Third Wave*, Alvin Toffler (1980) wrote about a growing phenomenon in which people would work from home in what he called “electronic cottages.” The practice of working from home was not a new concept in the 1980s, but it had not yet been widely recognized as a formal working arrangement. The term *telecommuting* was coined (Nilles et al. 1976) and has since become a lexicon in modern society to describe a variety of work settings that involve people who work from their homes on an occasional basis. By the late 1980s in offices around corporate America it was not uncommon to hear someone comment that he or she would telecommute on a given day.

Since that time, more specialized strains of telecommuting have evolved and have acquired their own monikers to denote a specific form of telecommuting. The term *telework*, for example, has traditionally indicated a formal telecommuting arrangement in which someone works full-time in a location outside a corporate center, which may include home, remote, or satellite office, or even “on the go” (Fritz, Higa, and Narasimhan 1995), although some research (Orlikowski and Barley 2001) has shown that the boundaries between working at home and working at the office have become blurred. The term *virtual* is often used to define the forms of distributed work that use information and communications technologies, or ICT, predominantly for communication and coordination (Lipnack and Stamps 1997) (Figure 1).

Because of its flexibility, virtual work is implemented in a variety of ways. The notion of “hotelling” grew out of a concept in which teleworking sales personnel, consultants, or repair technicians would share cubicles or offices with other teleworkers who may work in the office only

Figure 1: Virtuality and manifestations

a few hours a week. At Bank of America, for example, mobile loan processors travel to applicants' residences or places of business armed with laptop computers and document scanners to initiate loan applications. After a day's work, they return to the office to upload the applications data to the central loan office computer for further processing (Frigault 2000). In other arrangements, virtual workers have no permanent work location at all. At Kablelink, computer repair technicians work entirely from their trucks or vans equipped with GPS and are dispatched by operators who work full-time from their homes. The corporate office consists only of a receptionist, some computers, and a bank of telecommunications equipment used for handling and dispatching calls through the company's networks and mobile communications technology.

Many teleworkers work in "virtual teams," in which members are geographically and temporally dispersed. France Telecom's Orange division is a transnational organization serving in over 220 countries and territories and covering more than 140 nationalities speaking 70 languages. Orange employs a staff of over 4300 people who work in virtual teams on information technology solutions around the world. Because of its global reach and the dynamic nature of its business and geographically dispersed client base, Orange uses virtual teams for projects ranging from a few months to over a year that require specific expertise in a particular geography (Hyde 2004).

When Delta Airlines appoints Orange to install a network application at the airport in Auckland, New Zealand, a virtual team consisting of network engineers, security specialists, system architects and designers, network administrators, software designers and developers, business analysts, database analysts, hardware specialists, and a virtual team manager from various parts of the world, including France, Italy, India, Australia, the United States and the United Kingdom will collaborate from their respective parts of the world on the project using a variety of technologies ranging from e-mail to video teleconferencing. The virtual team will use a software application known

as a "change control system" to track and coordinate the changes each member of the virtual team makes to the system under development, along with technologies used in managing software and network revisions, called a "source control system." These technologies enable the various virtual team members to coordinate the technical aspects of their work, such as who is working on which task at a given time.

In "virtual communities" geographically dispersed people, or people who are homebound, who have shared interests and common goals participate with each other using the Internet (Wellman 1997). Unlike virtual teams, virtual communities are not a formal organizational structure but are instead informally initiated organically by community members, such as in open source software projects (Moon and Sproull 2002) or scientific collaborations (Finholt 2002). People may belong to many virtual communities, and their memberships may change regularly. Virtual communities emerge "when enough people carry on public discussions long enough, with sufficient human feeling, to form webs of personal relationships in cyberspace" (Rheingold 1994, 5).

The Rise of Telework and Telework on the Rise

From its inception, telecommuting offered many benefits to employees, business, and society at large. Employees generally experienced less interruption in their tasks and concentration, they spent less time commuting, and found a better balance between work and family life (Hill et al. 1998). Coupled with rising facilities costs and fueled by tax incentives resulting from legislation such as the Federal Clean Air Act of 1990 and the Intermodal Surface Transportation Efficiency Act of 1991, business executives saw virtual work as a means for gaining efficiencies, and the flexible work environment enabled companies to get closer to their customers, yielding a strategic advantage (Katz 1997; Lococo and Yen 1998). Many companies reported productivity increases by as much as 34 percent and increases in revenues by as much as 19 percent (Katz 1997; Turban, McLean, and Wetherbe 1996). Yet it was not until the mid-1990s, when technologies and remote working processes had matured sufficiently to effectively support virtual work, that they evolved into more formal arrangements and flourished (Chakravarthy 1997).

Now, with more than 10 million in the United States alone, estimates are that over 34 million people throughout the world are full-time teleworkers, a phenomenon that is experiencing an annual growth rate of between 5 and 10 percent (Bureau of Transportation Statistics 1992; Gartner Group 2000) with the vast majority of teleworkers working in virtual teams (Earley and Mosakowski 2000; Miller 1999; Wallace 1998). Virtual teams are becoming so pervasive that they are being called a "workplace revolution" (Daniels, Lamond, and Standen 2001) and are now commonplace in the United States, United Kingdom, and Western Europe (Hertel et al. 2004; O'Hara-Devereau and Johansen 1994), and they are emerging in India and Asia and many other parts of the world (Gartner Group 2000; Gibson, Zellmer-Bruhn, and Schwab 2003). Indeed, the traditional exclusively proximal team is becoming

increasingly rare in organizations, and most professional teams now consist of mixtures or degrees of virtual work (Bell and Kozlowski 2002; Martins, Gilson, and Maynard 2004).

Although the developments of telework and virtual teams have been impressive, they have not been without problems. Implementation rates have fallen short of many projections (Ruppel and Howard 1998), and between 25 and 50 percent have failed to live up to either employee or employer expectations (Fusaro 1997; Jarvenpaa and Leidner 1999; Wallace 1998). In some cases, employees who had been successful in a traditional proximally located team were unable to cope in a telework or virtual team environment, and employers reverted from using virtual work back to a traditional office setting (Workman, Kahnweiler, and Bommer 2003).

Although there are many reasons to expect businesses to escalate the implementation of telework and virtual teams, problems are expected to persist when there is a mismatch between employee and environment fit, or the proper steps are not taken to adequately support the virtual work or worker (Kozma 1991; Wieland 1999). As Toffler (1980, 215) warned, "One should not underestimate the difficulties entailed in transferring work from its locations in factory and office to its location in the home. Problems of motivation and management, of corporate and social reorganization will make the shift both prolonged and, perhaps, painful. [And] not all communication can be handled vicariously." To capitalize on the benefits and mitigate the pitfalls of virtual work, we must draw on explanatory theory to help us better understand both their strengths and their weaknesses.

THEORETICAL FOUNDATIONS AND THE NATURE OF TELEWORK

In most cases, people do not work entirely alone. Even those who are self-employed communicate with customers, vendors, or other trading partners. It is just as likely that people in organizations work in groups or teams. The membership in these teams may be stable or transient, and the durations of their assignments may be temporary or permanent (Mohammed, Mathieu, and Bartlett 2002). As people work together, the extent to which they are interdependent on one another is a product of the complexity of the tasks they perform accompanied by the degrees or intensity of the communications shared (Griffin, Patterson, and West 2001; Mohammed et al. 2002). Different levels of task complexity may require certain forms of team structures such as pooled, sequential, or reciprocal (Bell and Kozlowski 2002), which in turn rely on certain kinds of collaborative relationships to succeed (Shaw and Barrett-Power 1998).

However, it is becoming commonly recognized that the nature of telework differs from the traditional office environment, where workers are proximally located, and therefore differing team characteristics may be needed to support collaboration. One of the contributing factors comes from the technology media used to support collaboration that may span geographies, cultures, time, and time zones (Malhotra, Majchrzak, and Carman 2001;

Townsend, DeMarie, and Hendrickson 1996). Hence, it is often distance that necessitates the use of technology media for collaboration, and not necessarily social or convenience preferences. The resulting constraints on the collaboration may not always be a matter of choice. Therefore, it is important to understand how these collaborative conditions affect perceptions and performance in virtual work.

When people collaborate, information is conveyed through various channels linguistically with the words we say, paralinguistically through intonations and verbal patterns in speech, and nonlinguistically with eye gaze, posture, gestures, and signs such as blushing. For instance, a shift in eye gaze may signal turn taking or it may mean disinterest in the conversation. Having more information by way of the various channels helps us to fully grasp the meaning. Together, these channels create a shared communicative context (Fussell and Benimoff 1995), and drawing from this context our collaboration evolves from communicating information and ideas into negotiating the meanings and ultimately into a consolidation of shared understanding (Jehng 1997).

In a seminal study of computer-mediated collaboration, Murnighan (1981) identified a number of outcomes in proximal interaction versus communication over a technology medium. Specifically, as proximal contact decreased and technological intermediation increased, the number and quality of ideas increased. However, the number of conflicts also increased along with increased task (versus relationship) focus of the collaborators, while social pressures and group cohesion decreased. Carrying over into virtual work, three theories help to explain these phenomena and define the nature of telework. These are discussed below.

Theory Foundations

The ICT used in virtual work broadly include those such as e-mail, instant messaging, video conferencing, digital libraries, and databases, along with a host of applications for planning, managing, and executing work. One of the key aspects of contemporary ICT is the addition of interactivity in data processing and communications functions. The ICT mechanisms differ, however, in their capacities to transfer information. Information richness theory (Daft and Lengel 1986) explains how technology media affects collaborative exchanges in virtual work. Some forms of media are inherently richer than others owing to their capabilities to convey information. As an example, the telephone is capable of transmitting only about 37 percent of the sound frequency that the human voice can emit (Carr and Snyder 1997); thus, it can be difficult in some telephone conversations to detect subtle emotive nuances such as the difference between excitement and agitation, or boredom and relaxation, particularly without a visual component (Raghuram 1996).

An ICT such as video conferencing is considered a rich medium according to information richness theory, because it conveys many channels of information and more closely resembles face-to-face interaction than a leaner technology medium. By contrast, lean media such as e-mail have few channels through which information

is passed (Daft and Lengel 1986). Media used in collaboration therefore places various constraints, and to varying degrees, on the communicative context shared by collaborators. However, it is important to note that people, depending on their personal and social characteristics, differentially perceive this truncation of communicative context. For example, Carlson and Zmud (1999) expanded on the media richness concept by suggesting that one's experience with the technology and with those with whom one communicates means that more expressive messages can be transmitted over lean media, enhancing the perceptions of richness (Ngwenyama and Lee 1997). The communicative constraints in a virtual environment can elevate the level of ambiguity in the mental concepts people form during collaboration while other aspects attenuate social forces (Workman 2005). As an illustration, in telephone conversations more cognitive effort is spent making inferences about information that otherwise comes from visual cues and paralinguistic voice channels truncated in the telephone transmissions, which can raise the levels of ambiguity about both tasks and interpersonal relationships as we try to figure out "where the other person is coming from."

The impact of ICT on cognition and social activity is partly explainable by social influence theory (Deutsch and Gerard 1955), which postulates two forms of social influences: normative influences that are used to levy or gain approval or avoid rejection such as with peer pressure, and informational influence that stems from efforts to acquire accurate perceptions such as when seeking expert advice. The power of social influence increases as the intensity of the interaction with one another increases (Shaw and Barrett-Power 1998; Suzuki 1997; Workman 2001), and this governs communication and cooperative behavior (Hertel et al. 2004; Kraut et al. 1998).

As people cooperatively interact, they undergo a variety of social influences that shape perceptions as well as performance (Shaw and Barrett-Power 1998; Smith 2005). Social influences determine how shared meaning is co-created and structured using the participants' social systems as they collaborate (Suzuki 1997). As the intensity of interaction increases, people tend to become increasingly cohesive and their ideas become increasingly congruent (Jehng 1997).

Where social influence theory explains the collaborative behavior within groups, social forces also help to govern collaborative behavior across both formal and informal groups. Social identity theory (Tajfel and Turner 1986) explains how in-group/out-group boundaries are defined (Chen, Brockner, and Katz 1998; Heald et al. 1998) and is concerned with three components: categorization, identification, and comparison (Tajfel and Turner 1986). Social identity theory thus determines the "thickness" of group boundaries that divide an in-group from out-groups, and this helps to determine how cooperative people are in their behavior. As group members are socialized into a group, they undergo deindividuation, resulting in a loss of individual identity concomitant with acquisition of a group identity (Zajonc 1969). As such, social identity defines the ways in which and the extent to which people collaborate and cooperate with those outside the group.

As a consequence, the degree to which people cooperate and comply with the demands of a group depends on the weighting they place between personal and social knowledge acquired from the group's socialization processes (Gass and Seiter 1999; Zajonc 1969). When technology intervenes, it reduces the channels of information to varying degrees that enable group identity to form and the extent to which social influences affect one's perceptions and behavior.

A side effect of the information channels constraint with ICT is that it sometimes conspires to depersonalize the social environment, which can lead to objectification (Moscovici 1984), and objectification amplifies comparative dissimilarity in which people categorize others who they perceive to be unlike themselves in abstract terms or stereotypes (Tajfel and Turner 1986). As such, low social identity and low social influence result in more conflicts within the group, whereas high social influence and identity result in more conflicts with out-groups (Heald et al. 1998; Shaw and Barrett-Power 1998). Combined, these factors help to define the nature of virtual work.

The Nature of Virtual Work

As suggested by the theory, research (Martins et al. 2004) has shown that the nature of virtual work is more solitary than traditional office-based work due in part to the fact that there are reduced formal and informal interactions in virtual work than would normally take place in an office setting (Ellison 1999), and that the interactions that do take place are somewhat different from those in a typical office setting because of the constraints placed on how people communicate and coordinate their work (Jehng 1997; Raghuram 1996). Although people react differently to this environment, some virtual workers have reported that this solitary environment sometimes creates in them a feeling of remote isolation (Konradt and Schmook 1999; Turban et al. 1996), and there are tendencies for people to objectify virtual others, sometimes causing unusual hostility and alienation (Hertel et al. 2004; Wellman et al. 1996), while others are quick to trust and form rapid ties in a virtual setting (Jarvenpaa and Leidner 1999).

In addition to having the potential to increase solitude, virtual work is also less externally structured. Since virtual work is typically done remotely and communication is constrained to varying degrees by the richness or leanness of ICT, there are fewer opportunities for virtual workers to share or model coworkers' approaches to tasks. This necessitates individual approaches to doing things (Hill et al. 1998; Jehng 1997; Wieland 1999). As Baruch and Nicholson (1997, 23) found, "Some people may feel anxious and ill-at-ease without the reassurance of feedback from locally present management. Individuals with high needs for certainty may feel disoriented when confronted with the high discretionary environment of homeworking."

In addition to the more solitary and unstructured nature of virtual work there are also increased levels of ambiguity in terms of tasks and interpersonal relationships (Workman 2005; Workman et al. 2003). As people collaborate on problems, they use the information they gather to help formulate mental concepts and understanding to

guide their choices and decisions. The varying amounts of information constriction from ICT have some universal effects in raising cognitive ambiguity (Kraut et al. 1998; Montgomery 1999) but there are also differences in how people react individually to these effects (Lim and Benbasat 2000; Montgomery 1999). It is interesting to note that while sometimes ICT-mediated interaction may lead to objectification and greater levels of conflict than in a proximal setting, at other times people may form unqualified and unbridled intimacy with virtual others (Workman 2007).

HOW DOES TELE- WORK?

Since there are so many different ways virtual work can be conceptualized and implemented, for the purpose of simplification let us define “virtualization” as the degree of technological intermediation versus proximal interaction. Technological intermediation subsumes interdependence and communications intensity regardless of whether one is self-employed, working only with a superior or subordinate, or working in a group or team; or whether the reasons for virtual work are geographical, organizational, or for convenience. Working from this definition we can imagine a variety of implications for the individual, organization, and society from the personal and social effects from increasing virtualization as identified by Murnighan (1981) (Figure 2).

When virtualization increases, some people tend to perceive higher degrees of flexibility and control over their time, along with greater empowerment and increased responsibilities, although there may be increases in misunderstandings and greater role ambiguity and goal conflict (Hertel, Geister, and Konradt 2005). Organizationally, there may be greater efficiencies, lower overhead costs, and better responsiveness to customers or pressing needs. However, there may be greater complications in overseeing and managing the dispersed community of resources

in terms of people, information, and equipment (Lipnack and Stamps 1997). On a societal scale, virtual work may serve to better integrate disadvantaged persons or those with family care commitments into the workforce, and it may reduce environmental impacts from commuting traffic, gasoline consumption, and air pollution. On the other hand, it may also serve to further divide those who have from those who do not have the educational or other resources to work independently from home or on the go (the so-called digital divide). It may also place in greater jeopardy the security of information or other vital societal resources (Davis and Botkin 1995).

Managerial Oversight

To help maintain the balance among the multiple competing forces and address the complications with virtualization, managerial oversight is crucial. Traditional proximally located work and virtual work share many characteristics. Workers must communicate, plan, and allocate subtasks; sequence, schedule, and coordinate the work; problem-solve; derive products or solutions; and monitor performance (Bell and Kozlowski 2002), and their effectiveness is frequently based on productivity, efficiency, and adaptability (Chakravarthy 1997). Still, because of the nature of virtual work, there are some unique managerial considerations regarding individuals and teams as virtualization increases (Bailey and Kurland 2002). A useful managerial framework is called the GRIP model, representing goals, relationships, information, and processes (Hofstede 1998; O'Hara-Devereau and Johansen 1994) (Table 1).

Process-oriented teams are mechanistic in nature (Burns and Stalker 1961) and are concerned with the means by which goals are pursued. Their focus is on process improvement, and they tend to have many elaborate written processes and procedures stipulating how work is to be carried out. They work to standardize, eliminate variance, and reduce ambiguity (Hofstede 1998). On the other hand, results-oriented teams are concerned with the end products or services, and are organic in nature (Burns and Stalker 1961). Their focuses are on action and end goals, and their work is such that ends may justify the means (Daft 1998; Hofstede 1998).

Studies of proximal work (Daft 1998; Wageman 1995) have suggested that results-oriented teams may be more suitable than process-oriented ones because they enable tasks to be adjusted and redefined according to situational variables. However, this assumption relies heavily on the ability to make quick and effective decisions about courses of action (Daft and Lengel 1986). As indicated earlier concerning the nature of virtual work, virtual teams have less externally supplied structure than do proximal teams because of physical distance and time lags in communications, as well as constrictions of media richness by various technology bandwidths that facilitate remote communication (Workman et al. 2003). Also in virtual teams, both formal and informal interactions are reduced, which may elevate the ambiguity of some tasks and may increase indecision about courses of action (Jehng 1997; Wieland 1999).

To help compensate for this heightened ambiguity, people often turn to formal structures such as rules and

Figure 2: Attributes and characteristics

Table 1: GRIP Characteristics

Dimension		Attributes	Outcomes
Goals and processes			
	Process-oriented	Many written procedures	Highly structured, means-oriented
	Results-oriented	Few written procedures	Low structure, ends-oriented
Managerial/company relationships			
	Tight control	Centralized decision making	Strict hierarchies, formal
	Loose control	Decentralized decision making	Autonomy, informal
Employee relationships			
	Employee-centered	Collectivistic	Negotiation and consensus, feedback from others
	Job-centered	Individualistic	Independence, feedback from nonsocial sources, e.g., documentation
Information flows			
	Open teams	Thin, permeable team boundaries	Highly interdependent, much intra-team information flows
	Closed teams	Thick, impermeable team boundaries	Low interdependence, little intra-team information flows

procedures. However, when rules and procedures are lacking in an organization, people tend to use the organizational hierarchy as the primary method for managing group goals, and disputes are settled by referring problems to a common superior (Daft 1998; Griffin et al. 2001). In the absence of these supports, people find their own way through the system to figure out what to do. Because the interaction among virtual team workers and management is constrained by the nature of virtual work, increasing the specificity of the goals, processes, rules, and regulations augments the structure within the virtual team (Griffith, Sawyer, and Neale 2003; Montoya-Weiss, Massey, and Song 2001). Stated simply, the increased ambiguity and solitary nature of virtual work elevates the need for increasing process and procedural specificity. Unlike proximal teams, in which members often freely interact to derive team norms and behaviors and their contemporaneous nature better facilitates agility, effective virtual team performance requires specification “not only of individual team member roles but also the interrelationships between the roles of team members” (Bell and Kozlowski 2002, 41).

In a similar fashion, tighter control is also important in virtual teams. Tightly controlled teams have strict management hierarchies, and decision making tends to be centralized, whereas loosely controlled groups are more autonomous. Decision-making authority tends to be decentralized when loosely controlled and the decisions tend to be emergent and adaptive (Hofstede 1998; Moses and Stahelski 1999; Murnighan 1981). As autonomy increases, ambiguity increases concomitantly in a setting mediated by technology (Jehng 1997; Lim and Benbasat 2000), and this can have a negative impact on virtual team performance (Conner 2003; Montoya-Weiss et al. 2001).

Because virtual teamwork is less structured than proximal teamwork, and there are greater degrees of uncertainty, virtual team leaders must provide additional clarity and direction than might be necessary in a proximal setting (Workman 2005). The tighter control enables virtual team leaders to clarify contextual factors critical to performance management, including the ability to address work processes conducted by virtual team members with disparate worldviews (O'Hara-Devereau and Johansen 1994). According to Bell and Kozlowski (2002, 27), virtual team leaders must “closely monitor any changes in the environmental conditions. Because virtual team members are distributed, they are less aware of the broader situation and the dynamics of the overall team environment. So, as external conditions change such as in the case of modified task specifications or a new deadline or changes in the team's goals, managers need to facilitate adaptive and appropriate changes within their team.”

When it comes to working relationships, employee-centered teams operate on the principle of consensus and are collectivistic in nature. They derive feedback from teammates and work together on problem solving, and in employee-centered teams, work sequencing tends to be negotiated (Hofstede 1998). On the other hand, job-centered teams sequence work according to management directives or by means of expert power (Eby and Dobbins 1997). They are individualistic in nature, operate on the principles of efficiency, cost, and time (Hofstede 1998), and derive feedback from nonsocial sources such as a computer or documentation while people work by themselves on problems and tasks (Workman 2001).

These types of relationship interdependencies flow over into the information intensity of the team. Research (see, e.g., Griffith et al. 2003) shows that to compensate

for informational gaps created by technology mediation, distance, and time lags, more attempts are made at peer-group referencing in a virtual setting “as compared with individuals working within proximity of similar comparison others; [and] individuals within a virtual context will engage in more attempts at selecting referents outside of the organization” (Conner 2003, 141) to assess the distribution of workload, task progress, and fairness in relation to distributive justice (Conner 2003; Lipnack and Stamps 1997). This increases the need for horizontal and spatial linkages, which are dependent on how open a team is to cooperating and sharing information.

In a closed team there are thick boundaries between in-group and out-groups. They are highly compartmentalized, with few linkages, which constrain interdependence (Suzuki 1997). The thick boundaries between a closed team and other organizational units regulate the information flows, reducing information intensity horizontally and spatially. An open team is transcendent, has many information-intensive linkages among groups, and facilitates interdependence. Boundaries between the in-group and its out-groups are thin and permeable, intensifying the exchange of information horizontally and spatially (Hertel et al. 2004; Hofstede 1998; Mohammed et al. 2002).

Since virtual teams must rapidly assemble and import eclectic information to accomplish their tasks across functional, divisional, geographical, and time spans (Griffith et al. 2003; O'Hara-Devereau and Johansen 1994), and since virtual team assembly occurs with the involvement of many departments, such as human resources and line managers (Hyde 2004), open teams with permeable boundaries best facilitate information flows to support the dynamic nature of virtual work (Bell and Kozlowski 2002; Cole, Schaninger, and Harris 2002).

Employee Development

As discussed previously, research (Ellingson and Wiethoff 2002; Jarvenpaa and Leidner 1999; Maruping and Agarwal 2004) on the nature of virtual work and the person-environment fit suggest supplementing the virtual environment by providing additional structure and specificity to that typically found in a proximal work setting. Beyond these environmental factors, employee development is an important consideration both in terms of preparing people for virtual work as well as during virtual work (Hertel et al. 2005). Preparatory development may involve the knowledge, skills, and abilities that are specifically related to the virtual work environment, while ongoing development may include supplementing occupational knowledge and skills ordinarily acquired from observational modeling and other proximal learning.

In addition to the competencies needed for work in general, virtual workers may also benefit from the development of “telecooperation” skills (Duarte and Snyder 2001; Ellingson and Wiethoff 2002; Jarvenpaa and Leidner 1999; Lipnack and Stamps 1997) acquired through self-management training and by providing substitutes for leadership along with acculturating mutual trust. Self-management is comprised of independence, persistence, and creativity (Staples, Hulland, and Higgins 1999). An independent worker is self-motivated and is able to

plan and organize activities with little external support. Persistent workers have high endurance toward goal achievement and continue working after interruptions (Hertel et al. 2005). Creativity involves the ability to work with novelty and derive unconventional solutions to unconventional problems (Jehng 1997; Kozma 1991; Wieland 1999), which is an important coping mechanism, given that the nature of virtual work makes observational modeling difficult and produces a highly novel working environment (Workman et al. 2003).

With increasing virtuality, mutual trust is reduced (Maruping and Agarwal 2004); therefore, building trust is especially important to the potential success of virtual teams. Trust-building techniques include face-to-face kick-off workshops (Duarte and Snyder 2001), sponsoring and facilitating informal communications (Saphiere 1996), and clarifying rules, roles, and structure to reduce potential conflicts (Duarte and Snyder 2001; Hertel et al. 2005). These techniques generally require a significant amount of time, so their effectiveness is improved when team members have predispositions for trust that aid the development of a positive team climate (Hertel et al. 2005).

Regulatory Compliance, Laws, and Corporate Policy

Accompanying oversight and employee development are specifications of regulatory compliance and policy. There are many regulations and laws that govern various aspects of home offices and home-based worksites. Some of these address criminal activity, some civil, and others sociopolitical elements of the law. International work laws vary widely, and in the United States they are changing rapidly. Managers should investigate the laws and regulations for their locale and jurisdiction. Some public policies and regulations that affect telework in the United States are specified by the federal Department of Labor. This body oversees regulatory agencies such as OSHA, Bureau of Labor Statistics, and Worker's Compensation. Although there are other agencies (mainly at the state level), the federal Department of Labor has the primary responsibility for public regulation of telework at large. State agencies (the state departments of labor, for example) should also be consulted about specifics for a given state. There are some legal considerations, such as privacy and ownership rights, to consider as well. In addition, there may be policies that affect telework in a specific industry defined by the Environmental Protection Agency, the Department of Energy, the National Telecommunications and Information Administration, and the Bureau of Transportation.

For the purposes of this chapter, the following brief discussion will be confined to some key regulatory and legal issues regarding electronic transmission of information, official records, video teleconferencing, and surveillance. As with many of these issues, a concern for a traditional office environment is a concern as well for virtual work; however, in terms of information ownership and chain of custody, information that might not normally pass over a public wire may be more subject to this mode of transmission in virtual work.

It is important to note that international work laws and regulations vary widely, and in the United States, the laws that affect virtual work are changing rapidly. In the United States, the federal Department of Labor specifies many of the public policies and regulations that affect virtual work. State agencies such as state departments of labor may also define virtual work regulations, and there are regulations that affect virtual work in a specific industry such as the Health Insurance Portability and Accountability Act (HIPAA). Local zoning laws may also apply.

Most messaging systems use store-and-forward, and the World Wide Web caches files on intermediate servers. These media create multiple intended and unintended recipients of information copies, which create several potential problems for virtual work. The precise effects and importance of these problems depend largely on the kinds of virtual work done, the industry, and the kinds of information being used. For instance, there will be a greater impact if virtual workers are operating with sensitive or official information such as government, financial, or health care records than if they are simply reporting their time over the Internet.

Because electronic information products are intangible (Borrull and Oppenheim 2004), there is no good way to determine whether they have been altered unless digital signatures are used. Sensitive information may "fall into the wrong hands." In the case of store-and-forward messaging, the legal recourse and process of adjudication is complicated, and in some cases unclear, especially if an infringement occurs across international boundaries. For instance, unless information is protected with encryption, it has not been legally determined what limitations and liabilities are applicable to redistribution of information by intermediaries on the Internet (Bureau of Transportation Statistics 1992; Akdeniz, Walker, and Wall 2000). As suggested, the best safeguards against most of these problems are to use digital signatures and cryptography, although this is not always possible. For certain kinds of documents the techniques used in digital rights management such as watermarking and recording document usage may be beneficial.

Another issue for virtual work involves official "records" and e-mail. In most traditional office settings the messaging infrastructure is under the control of the company, but in a virtual work setting the control often falls under Internet service providers. For example, the National Archives and Records Administration (NARA) has created regulations under the Federal Records Act (FRA) to prevent shredding or deleting certain kinds of e-mail. These regulations may have implications not only for e-mail considered federal records but also for a range of message types in the wake of the Microsoft antitrust litigation and the Sarbanes-Oxley Act (Borrull and Oppenheim 2004).

Some of the regulations address retention requirements, but several problems have not yet been resolved and include the fact that to comply, e-mail has to be modified to distinguish whether or not a document is a matter of federal record. Also, it has not been legally decided where responsibilities lie with regard to maintaining detailed audit trails of messages that traverse systems in the Internet. In addition, organizations that fall under the FRA regulation must specify locations of all documents.

This is a problem for distributed databases, home or remote locations, intermediaries, if data is mirrored, if documents have multiple parts or attachments, or if they are WAV, GIF, or JPEG files (Matteson and Feldstein 2005).

In terms of videoconferencing and surveillance, one of the central issues concerns the right to privacy versus the right to know. Laws have tended to support the rights of corporations to inspect and monitor work and workers, which arises from needs related to business emergencies and the corporation's rights over its assets and to protect its interests (Borrull and Oppenheim 2004). Employees may use e-mail or the Web inappropriately for purposes such as disseminating harmful information, infringing on copyrighted or patented materials, harassment, corporate espionage or insider trading, or acquiring child pornography. In these instances, the courts have leaned on the principle of discovery to allow inspection, granting any party or potential party to a suit, including those outside the company, access to certain information, such as e-mail and backups of databases, even to reconstruction of deleted files. The idea has now evolved to the use of video for surveillance (Bureau of Transportation Statistics 1992).

The Electronic Communications Privacy Act defines an "electronic communication" as any transfer of signs, signals, writing, images, sounds, data, or intelligence of any nature transmitted in whole or in part by a wire, radio, electromagnetic, photoelectronic, or photooptical system that affects interstate or foreign commerce, but it does not include the radio portion of a cordless telephone communication that is transmitted between the cordless telephone handset and base unit, wireless networks, any wire or oral or video communication, any communication made through a tone-only paging device, or any communication from a tracking device (Losey 1998). The original intent was to protect people from the interception of communications not otherwise subject to interception. However, the U.S. Patriot Act (HR 3162) has vastly expanded the powers of government and enforcement agencies to conduct surveillance and communications interception pertaining to criminal activity (Borrull and Oppenheim 2004).

Beyond the criminal concerns about virtual workers' activities, in some cases employers have chosen to use video teleconferencing to monitor worker productivity. Although surveillance in home offices carries special right-to-privacy considerations (Theuman 2005), from a virtual work standpoint, the use of video teleconferencing to monitor work activity may be supported by an analogy to the "plain view" doctrine, which allows the rights of a company to monitor employees in plain sight as long as the company takes overt action to notify its employees (Borrull and Oppenheim 2004).

The extent of an employee's expectation of privacy often turns on the nature of an intended intrusion. With the exception of personal containers, there is little reasonable expectation of privacy that attends to the work area. That is, a worker may have reasonable expectation of privacy in personal possessions such as a handbag in the office, but the law holds that employers possess a legitimate interest in the efficient operation of the workplace and one aspect of this interest is that supervisors may monitor at will that which is in plain view within an open work area (Braithwaite and Drahos 2000). This position

is strengthened if an employer acts overtly in notifying its workforce in advance that video cameras would be installed and used for that purpose. Consequently, it might be legally possible to use video teleconferencing for monitoring work activity in the home as long as certain safeguards are observed (Akdeniz et al. 2000).

Security

In many if not most cases, virtual workers are provided with company-owned computer equipment and software and have in their possession documents and data and other information that may be proprietary or confidential. In addition to the obvious and well-publicized damages that can occur from security breaches, one of the key issues concerns downstream liability, in which companies may be held liable for surreptitious actions that are taken using their equipment, even if those actions are not known to the company or are unauthorized by them. This liability may well extend to virtual work settings unless there is a due diligence effort to preclude it from happening (Borrull and Oppenheim 2004). As a result, there are important considerations for virtual work that include how to control access to networked resources both resident on virtual workers' machines and the ones they may access at corporate locations. Basic security technologies such as firewalls, cryptography and authentication software, and virus and spyware scanners are important in the defense arsenal. Yet, although many security controls exist to help maintain information security, people frequently do not use these technologies to secure their systems even when they know how to use them and that they are readily and often freely available (Hochhauser 2004; Ives, Walsh, and Schneider 2004).

When people lack the skills necessary to use security technology and indicate that they would be willing to pay a fee to have their information protected by a third party, in practice they often do not avail themselves of the opportunity (Acquisti and Grossklags 2003). Thus, there exists a classic "knowing-doing" gap relative to information security, which is exacerbated in a virtual work setting.

Research (Woon, Tan, and Low 2005) has shown that people implement security measures with greater consistency when the security threat is perceived as more severe than when a threat is seen as innocuous, especially when a severe threat is also perceived as imminent. Other important factors in whether virtual workers implement security measures include whether they feel that their security actions will help prevent a security incident (Pahnila, Siponen and Mahmood 2007).

One of the greatest security threats comes from covert actions taken inside a company by its own employees (Blackwell 1998; Bresz 2004). Employees have the greatest access to sensitive information, and company insiders may also have extra motivation and opportunity for committing crimes using private business information.

Thus, managers of virtual teams must first increase employee awareness of security threats (Calluzzo and Cante 2004), provide training on security technology, processes, and procedures (Straub and Nance 1990), inculcate ethics and spell out clearly the consequences for misbehavior (Harrington 1996; Hsu and Kuo 2003;

Kurland 1995), and develop clear and comprehensive security policies that govern the behaviors of individuals within organizations as well as the technological defenses (Schlarman 2002).

The SANS Security Policy Project (SANS 2005) provides common security practices, and beyond the technological components, its recommendations include ethics and information security awareness as well as enforcement and punishment that attend to contravention from insiders. In any case, security policies need to address both behavioral and technological components of information security for virtual workers (Stanton et al. 2005).

Employee Agreements and Ways of Working

As ad hoc formation of norms might be constrained by the nature of the virtual environment, formalizing rules and behaviors will increase structure, leading to better performance (Daniels et al. 2001; Griffin et al. 2001; Montoya-Weiss et al. 2001). A way to accomplish this is to use employee agreements (Frigault 2000) and to develop policies and procedures that define ways of working (Hyde 2004). The contributions derive from formalizing preparations, establishing virtual project launch activities, developing guidelines for performance management, and laying out plans for team behaviors and development (Hertel et al. 2005). Other essential ingredients in successful virtual working are the identification of dependencies; ensuring that priorities in the project are well understood; making sure that financial, budgetary, and purchasing processes are identified; gaining a clear understanding of time and expense reporting; assessing risks; and determining the training, rollout, and support plans (Hyde 2004).

Thus, the best way to address the potential legal and other problems besides increasing process and political structure, training, and using security technology is to establish guidelines and have clear written policies and procedures that cover both employer and employee responsibilities (Frigault 2000; Hyde 2004). Corporate policies may include virtual worker responsibilities and assumed liabilities related to conducting work on behalf of the company from home, on the road, or in a remote facility including customer locations. These policies often delineate insurance coverage and liability, for example, that specify who is responsible for loss or damage to data or equipment used at home and who should be responsible for injury to third parties on virtual workers' premises. The use of personal versus corporate equipment, ownership of intellectual property, and information security are also generally addressed. It is common to designate aspects of the home office environment in a virtual work policy, and if policies include home inspections it is important to include how and when virtual workers are notified about inspections. Guidelines that govern landlord/tenant relationships in each state might prove to be useful, although inspections may increase employer liability if the company "certifies" a home office safe and a virtual worker is subsequently injured (Akdeniz et al. 2000).

In addition to covering the legal aspects of virtual work, many companies establish policies and procedures that define how employees are selected for or assigned to virtual

work, how they are evaluated, how work is allocated and coordinated among virtual collaborators, and how time and production are managed and monitored (Baruch and Nicholson 1997). In virtual projects, kickoff meetings are seen as crucial for educating virtual workers about policies, setting clear expectations, clarifying roles, and laying the groundwork for how the virtual project will be conducted (Lipnack and Stamps 1997). It is important to note that there are many instances in which good policies and procedures were "on the books" but were either improperly implemented or were not enforced. Unless established policies and procedures are enforceable and enforced, they are a detriment. Companies need to enforce the policies to protect business interests and themselves. If a company does not properly implement and enforce its policies, it opens itself up to claims of discrimination. Simply having a policy on the books is not an absolute defense.

IMPLICATIONS AND DIRECTIONS— CONCLUDING THOUGHTS

As technologies continue to mature, virtual work continues to develop into increasingly sophisticated forms. The maturation and richness of the technology is giving rise to the term *telepresence* to describe simulated environmental realism. By simulating a familiar environment and context, virtual workers become more comfortable with the computer-mediated form of work. The shared context also improves the consolidation of shared understanding (Jehng 1997) to better facilitate collaboration in virtual work. An example of telepresence is *KMi Stadium*, a suite of software applications used at the Open University's Knowledge Media Institute in the United Kingdom to model live events that give remote participants on the Internet a feeling of "being there." Auditory cues such as clapping, laughing, shouting, and whispering are embedded in the video stream to simulate the presence of a live crowd (Scott 2002).

By combining digital technologies, telecommunications and computer companies are creating new low-cost interactive multimedia products and services that provide voice telephony through cable networks, analog and premium TV broadcast, pay-per-view, and video-on-demand entertainment with teleshopping and telebanking businesses, which create new industries and business opportunities. These business models are incipient prototypes for virtual work. For example, when enLeague patented its new technology, company managers, programmers, systems architects, and patent attorneys across the United States used videoconferencing and streaming video to map out the schematics together; and for planning the Windward live-and-work community in Alpharetta, Georgia, cartographers, planners, and building contractors were better able to visualize landscapes and simulate noise levels using telepresence.

The delivery of broadband networking to the home and remote office has cheaply and reliably enabled commercial-grade communications from the home or remote work center, and multimode technologies that make use of these high-bandwidth communications allow virtual workers to choose the medium that best fits their tasks

and preferences. An example of this type of multimode flexibility involves the different uses of video teleconferencing in which people who prefer the full richness of the medium may have their conversational partners use the entire range of the visual, voice, and textual capabilities. For those who prefer leaner media, the shutter of the camera may be closed, leaving the voice and textual components, or the microphone may be turned off, and only the "whiteboard" capability of the medium used (Webster 1998).

Video teleconferencing technology is becoming widely available for the home user and ranges from sophisticated, multi-user technologies such as VSGI to inexpensive simple, single-user systems such as Intel's PC camera. In addition, rather than using traditional telephone service, virtual workers are frequently using the Internet for voice over IP, or VoIP, with applications such as Skype and Vonage, and new VoIP technologies are emerging to carry increasing amounts of data along with policy-based routing protocols to better support the nature of voice and video transmission.

There are interesting trends in wireless technologies also. Blackberry and Palm represent forms of powerful wireless personal mobile computing systems (PCS), and many of these devices come equipped to operate with products such as TeamCenter and Symantec's pcANYWHERE and pcTELECOMMUTE to support Web-based project management for overseeing access, tasks, projects, and teams. When the Best Buy company contracts technicians from InitiaTEK to install a new line of point-of-sale computers throughout its store chain, technicians log into a secure portal on the InitiaTEK Web site and use their Dell Axim PCS enter the project status, where it can be tracked over the World Wide Web by managers at both companies.

Applications in cellular phones currently support e-mail, Internet access, facsimile, and other basic services, and palmtop computers and IP phones are becoming powerful enough that they will soon be able to take the place of laptops for many applications. As third-generation or "3G" cellular phones and WiMAX take hold, there will be support for broadband services for mobile phones to enable fast Web access, streaming music, on-demand video programming, and videoconferencing.

The increasing sophistication of technology and the need for faster, better, cheaper business operations are co-evolving. The demand for richer and more flexible technology is enabling virtual work, which is creating a greater demand for richer and more flexible technology. This co-evolutionary drive toward more robust technology and more responsive business models is redefining what we have come to think of as "work." Fuzzier dimensions are supplanting the traditional boundaries that have defined the workplace, the designation of work times, and the fixed roles in normative occupational relations. Along with this new agility come risks that include a reduction in the ability to manage one's time, difficulties in supervising the health and safety of remote and mobile workers, constant intrusions from the myriad new communications media, and alienation from vital social and instructional ties at work. The success of virtual work in the future might quite literally hang in the balance.

GLOSSARY
